CHRPTER 1 BACKGROUND

1-1 General

Fig. 1-1-1 PHYSICAL REGIONS OF SIERRA LEONE

^{*} Tabken from "A New Geography of Sierra Leone", DRG Gwynne-Jones (1978)

Population

The FAO statistics of 1977 gave slightly bigger figures. The estimate in 1975 was $2,983 \times 10^3$. The annual growth rates estimated for the other periods are bigger, too. i.e, 2.41 for '70 - '75; 2.57 for '75 - '80; 2.64 for '80 - '85.

In the economic review of the Bank of Sierra Leone, the growth rates it uses are ca. 2.2% from 1974/75 to 1976/77, 2.1% for 1977/78 and 2.7% for 1978/79.

Table 1-1-1 TOTAL POPULATION AND ANNUAL GROWTH RATE

	1963	1974	Annual growth rate %	Density 1974 (/km²)	Sex Ratio in 1974 M/F X 100

CHAPTER 2 AGRICULTURE AND FARMING

2-1 General Affairs in the Project Area

Farm Household

The number of Farm Householders differs a little from the number of farm houses in the villages. The same differences are also occasionally seen in their land tenure. Such being the case, the farm householder or the farms cannot be exactly divided because large families are the custom.

So we have decided to regard the number of houses as equivalent to the number of Farm Households, which amounted to about 630. One Farm Household is a family of 11.4 and has 5.6 children on average in the project area.

Farming

The rice cropping accounts for about 90% of all produce in the villages. Generally speaking, the low stream part (the west area) yields better looking rice than the upstream part (the east area). Fishing is pursued as a side line in the villages, particularly in Katik.

Palm oil production is seen in every village, but not to such a degree that it can be sold in any amount to outside villages. Beside this, there are some tree-crops and some upland crops; Coconuts, Oranges, Mangoes, Cola-nuts, Bananas, Cassava, Yam. Beans, etc. which are mostly produced for self-sufficiency.

Rice Mills

There are 9 Rice Mills, the scale of which is almost the same as one or two mill machines.

The capacity of one machine is about 100 bushels of paddy rice a day.

The village memoranda are as follows (Table 2-1-1).

Vegetation

On the basis of vegetation, the swamp can be divided into mangrove swamps, sedge swamps and grass swamps. Most of the project area is located in the mangrove swamps, which are presently used for rice cultivation. Also some parts of the area are covered by a mixture of grass, reeds and rushes which form a typical swamp flora.

Regarding weeds, generally speaking, this area is remarkably free from weeds. Most weeds are killed off by the salty conditions in dry season.

The only durable weed is the creeper grass, "Kire-kire", which is pulled up while preparing the paddy fields. "Kire-kire" does not do much damage to the paddy field, providing the farmers weed it out annually.

2-2 Farming and Farm Household Economy Survey

2-2-1 The survey method

(1) Sampling method

The sample farmers were selected by village heads from amongst the willing farmers who attended the farmers' meeting held in three big villages Gbenti, Konta and Kagbulo. We also interviewed

Table 2-1-1 VILLAGE MEMO

all the householders in Mango Village.

The 41 selected householders are mostly the higher class farmers whose paddy field amount to 250 ha covering 30% of the rice crop area in the Project area.

The locations' map of the sample farmers is shown in Fig. 2-2-1.

(2) Questionnaires

Questionnaires (Table 2-2-1) were drawn up taking the farmers' rather limited abilities into account, for they have very little knowledge of weight and acreage.

Table 2-2-1 THE ITEMS OF QUESTIONNAIRES

I. Farming Practice

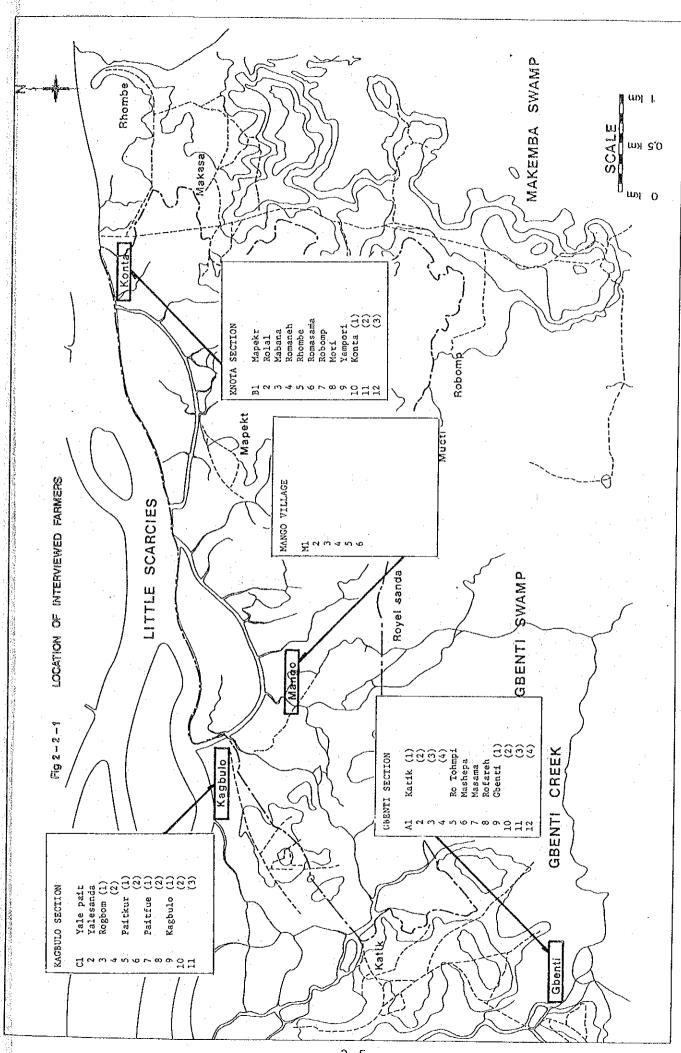

- A. Seed
- B. Sowing
- C. Seedling
- D. Transplanting
- E. Harvesting

II. Farm Household Economy

- A. Farm Family
- B. Property
- C. Labour
- D. Income and Expenditure for Production
- E. Cost of Living

(3) Duration of Inquiry

The 4 interviewers interviewed the farmers from Dec. 8, 1982 to Jan. 7, 1983 limiting the inquiries to the year of 1982. Every farmer was very friendly and co-operative, in spite of

the busy harvesting season.

2-2-2 Farming practices survey

The survey concentrated solely on rice cropping so here we will describe only the rice production.

(1) Varieties

The rice varieties cropped by sample farmers are shown in Table 2-2-2.

(2) Nursery

Every farmer answered all items on nursery (See Table 2-2-3).

The proportion of nursery area to paddy field is about 10% on an average. Most farmers commonly understand that one bushel of seed is sowed for one acre of field acreage. This acreage is not measured acreage, and farmers usually judge acreage by the quantity of seeds sown.

(3) Transplanting

Every item on transplanting was answered (See Table 2-2-4). Plowing twice for the land preparation is customary, but sometimes only once, when transplanting after September. Transplanting is effected by using a wooden or iron tool named "Dibra".

The common technique, trimming the top of the seedlings before transplanting, is observed in all the seedlings transplanted in June or July, but in 70% of seedlings after September.

(4) Harvesting

Harvesting survey is shown in the Table 2-2-5. Harvesting works, transportations and rice milling are usually paid for with harvested paddy. Farmers make it a rule to pay a 10% portion of the harvested paddy for harvesting work.

In this survey the reply to the average yield per ha was 1.256 t/ha (18.5 bu/acre) by sample farmers.

But every interviewer says that the sample farmer replied lower yields and higher costs or debts. Therefore, we have to review the yield per ha. It will be reviewed in 2-4-3 (Yield Survey).

(5) Cropping patterns

Fig. 2-2-2 shows the rice cropping patterns by the sample farmers.

Some farmers along the river were seen transplanting even at the beginning of December, but not among the sample farmers.

2-2-3 Farm household economy survey

(1) Rice production cost

The paddy rice production cost is composed of the following items (Table 2-2-6).

The cost of seeds is counted with the paddy price (Le. 10/bu) in the villages, although the governmental seed prices is Le. 15/bu. The cost of farming tools, paid wage, and transportation are counted with the average cost per ha among the

sample farmers.

(2) Rice crop labour

According to the sample farmers count, (The average scale is 6.2 ha), the labour utilization per ha is shown as follows (Table 2-2-7).

As to the hired labour, to clearly divide between genuinely outside hired labour and neighbours or relatives who are helping out, is impossible.

When we compare our findings with the Table 2-2-8 reported by Rokupr R.R.S. we can deduce the following facts.

- Total labour use in the Project area is nearly half the amount at Rokupr farm.
- 2) Land preparation and transplanting in the Project area are much easier than at Rokupr farm.

(3) The usage of harvested paddy

Harvested paddy is disposed of as follows (Table 2-2-9). Repayment of debts, owing to living expenditure and in a smaller measure to production costs (wages, etc), are not all fulfilled. Presents cannot be distinguished from wages and interest on debts, because paddy is given to neighbours as interest on debts as well as for their labour, because the farmers have no money.

(4) Farm household income

Gross income per ha by paddy cropping is Le. 699, counted from the estimated yield in 2-3-2 (Yield survey).

Net income per ha by paddy cropping is counted as

Table 2-2-8 LABOUR UTILIZATION (M.D./ha)

follows. Le. 699 (Gross income) - Le, 126 (Production cost) = Le, 573.

The income from other crops is minimal as they are grown for self-sufficiency, and the answer to production costs for these outputs was given as "None" by every farmer.

Non-agriculture income stems mostly from fishing. Fishing nets are one of the few fishing costs.

The average income of one householder is estimated from 1.35 ha of the average scale of farming.

Table 2-2-10 shows the income and its origin, of the 41 sample farm householders (6.2 ha of the scale).

- 2-3 Additional Survey and Review
- 2-3-1 Seed selection by salty water

Table 2-3-1 shows the seed selection experiment by salty water. These values are the average ones taken from the same experiment conducted 5 times under the same conditions.

The local varieties are bigger in specific gravity and uniformly better in full ripening than the improved varieties.

This table means that the improved varieties are suitable for seed selection by the 1.12 of specific gravity, on the other hand, the local ones fit in with the 1.20 of specific gravity.

2-3-2 Yield survey

The 1.26 t/ha of the average yield, which was counted in the Farming Practice Survey, should be reviewed using other data.

We also tried to carry out the yield survey at several fields in Konta village. But this shows such varied values (60 g/m^2 - 600 g/m^2), that we cannot guess the mean yield.

According to many different reports, some of the mean yields per ha were reported as in Table 2-3-2.

Rokupr farm also reported that the mean yield on mangrove swamp rice was 1.63 t/ha with no fertilizer in the 1979, annual report (See Table 2-4-4).

With the above mentioned data, the average yield in the project area is estimated 1.9 t/ha.

2-4 Farming Plan and the Discussion

2-4-1 Cropping patterns and the choice of suitable varieties We have made up three alternatives (Fig. 2-4-1) for double cropping patterns in the Project area. These three patterns are evaluated in the following items (Table 2-4-1)

Table 2-4-1 THE EVALUATION OF CROPPING PATTERNS ALTER-NATIVES

2-4-2 Mechanization of the labour force

When we adopt the double cropping pattern, we have to solve the labour shortage which will be caused by concentrated cultivation. It will be necessary for farmers to prepare their fields all at once in the Project area (1,278 ha). Man power or working cattle are not fast enough.

Fig. 2-4-F ALTERNATIVES ON THE CROPPING PATTERNS

2-4-3 Fertilizer application and the yield

The paddy yield increases with Fertilizer Application. The proportional increase ratio depends on the type of fertilizer, method of application, soil and water condition, rice varieties, and so on.

Only nitrogen application could make the yield per hareach 3.0 t/ha or more, according to the Rokupr's report (Table 2-4-4).

Table 2-4-2 ALTERNATIVES ON TWO TYPES OF MACHINE

CHAPTER 3 HYDROGEOLOGY AND GROUNDWATER

3-1 General Geology

A relief of Sierra Leone is divided into three main regions eastward, i.e., a coastal plain, an interior lowland, and an interior plateau. Geology of Sierra Leone corresponds roughly with the topographical feature. The coastal plain is underlain by Bullom series which consists of Tertiary to Recent Formations. The interior region consists of Cambrian to Pre-Cambrian formation (Fig. 3-1-1).

The project area consists mainly of Bullom series, swamp deposits and lateritic deposits.

The Bullom series is composed of unconsolidated sediments with mixed layers of sand, silt, clay and gravel, with lignite. According to some lithological logs of MRT (1972), the thickness of these Bullom series sediments is about twenty meters at Katonga, which is about fifteen kilometers upstream from the project area, and is around fifty meters at Gbenti, which is five kilometers away southwestward.

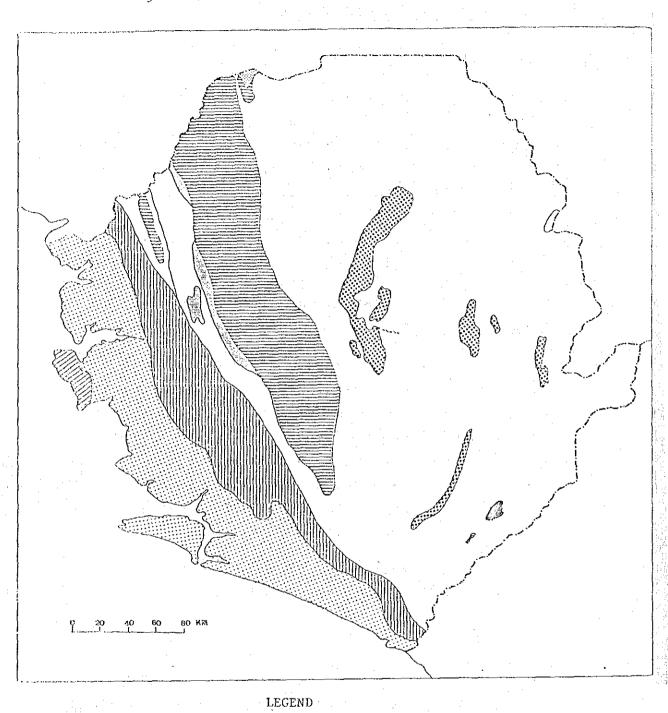

The Bullom series is underlain by metamorphic rocks which consist of gneiss and hornfels.

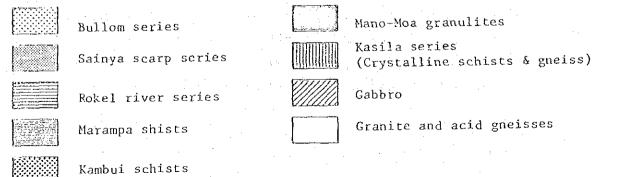

3-2 Hydrogeology

A hydrogeologically important formation in and around the project area is the Bullom series which consists of unconsolidated sediments, sand, gravel, silt and clay. Metamorphic rocks are considered to be an impermeable basement beneath the Bullom series.

Existing wells, which were dug up to a depth of five meters in the upper layer of Bullom series, are

rig. 3-1-1 GEOLOGICAL MAP

utilized as important water resources in the dry season in and around the project area. It is estimated from an observation of all of these wells that an aquifer of sands or clayey sands exists.

Lungi Airport Water Treatment Works, which is twenty five kilometers away from the project area, collects groundwater from the Bullom series through one gallery and two deep wells. It has been reported that one well was testpumped at 3,600 gallons per hour for a six feet drawdown. This discharge rate corresponds to a specific capacity of 210 m³/day/m. It is likely that the Bullom series has higher permeability.

There have not been data regarding pumping tests for an aquifer of the Bullom series, however, MRT (1972) estimated that the permeability was 1.4×10^{-3} ft/sec from a particle size analysis of sand layers. Further, as these sand layers are 15 m to 20 m thick according to a result of MRT-boring at Gbenti, if they distribute horizontally, it is likely that they can be a source for groundwater development.

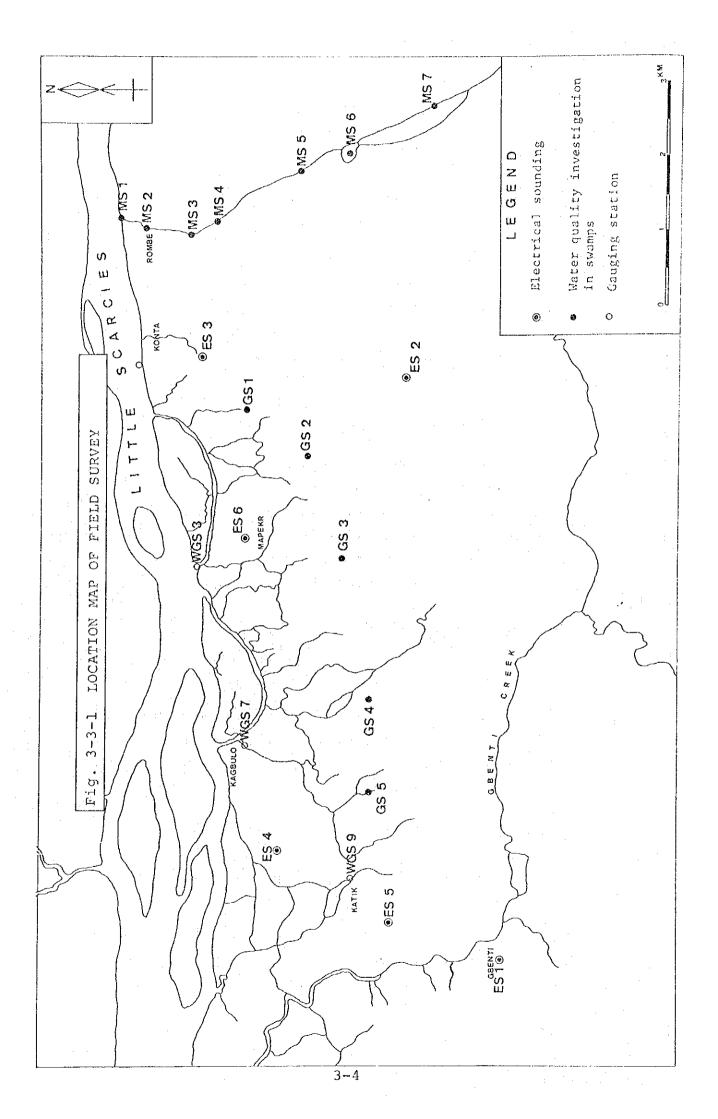

3-3 Electrical Soundings

In order to grasp a distribution of the Bullom series in and around the project area, electrical soundings were carried out at six locations. These locations are shown in Fig. 3-3-1.

3-3-1 Measurment of resitivity

The measurements were carried out by Geological Survey Section, Ministry of Mines.

As the surface condition was not good due to the dry season, the Schlumberger method, which has fewer number of electrode transfers, was applied for a distribution

of electrode. An average depth of sounding of about 100 m and an average AB line of 400 m were maintained throughout this survey. The soundings were carried out by means of an ABEM TERRAMETER SAS 366 operated by a 12.8 volt power source.

3-3-2 Results of soundings

Result of soundings shows multi-layer curves (Fig.3-3-2 to 3-3-4). These curves were interpreted by means of Schblumergers' standard curve and its supplementary curve. As a result, the project area was divided into three to five resistivity layers.

Based on lithological logs, these resistivity layers were estimated respectively as the following geological formations.

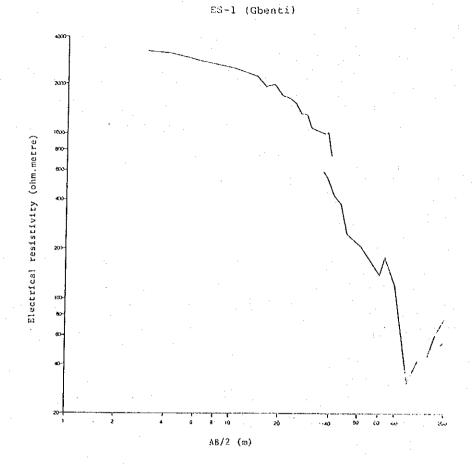

A layer, which was below 100 ohm-m, was assumed to be swamp deposits, clayey layer of the Bullom series or a weathered basement.

A layer, which was 100 ohm-m to 1,000 ohm-m, was assumed to be sands or clayey sand of the Bullom series.

A layer, which was above 1,000 ohm-m, was assumed to be lateritic sediments or a basement.

These results are shown in Table 3-3-1. Based on Table 3-3-1, a hydrogeological cross section was made as shown in Fig. 3-3-5.

An impermeable basement is encountered at a depth of 10 to 20 m around Konta and Mapekr and is encountered at a depth of 60 to 80 m around Kagbulo and Gbenti and its depth increases westward.

				J	

In the eastern part of the project area, swamp deposits or clayey layer of the Bullom series continue to the impermeable basement and there is lack of sand layer.

In the western part, a layer assumed to be a sands layer of the Bullom series distributes without clayey layer.

This sandy layer, which has a thickness of 25 to 50 m, is considered to be a surce for groundwater exploitation.

3-4 Groundwater

Sixteen existing wells which are located in and around the project area were surveyed for type, depth, usage, groundwater level and water quality. The locations are shown in Fig. 3-4-1 and the results are shown in Table 3-4-1.

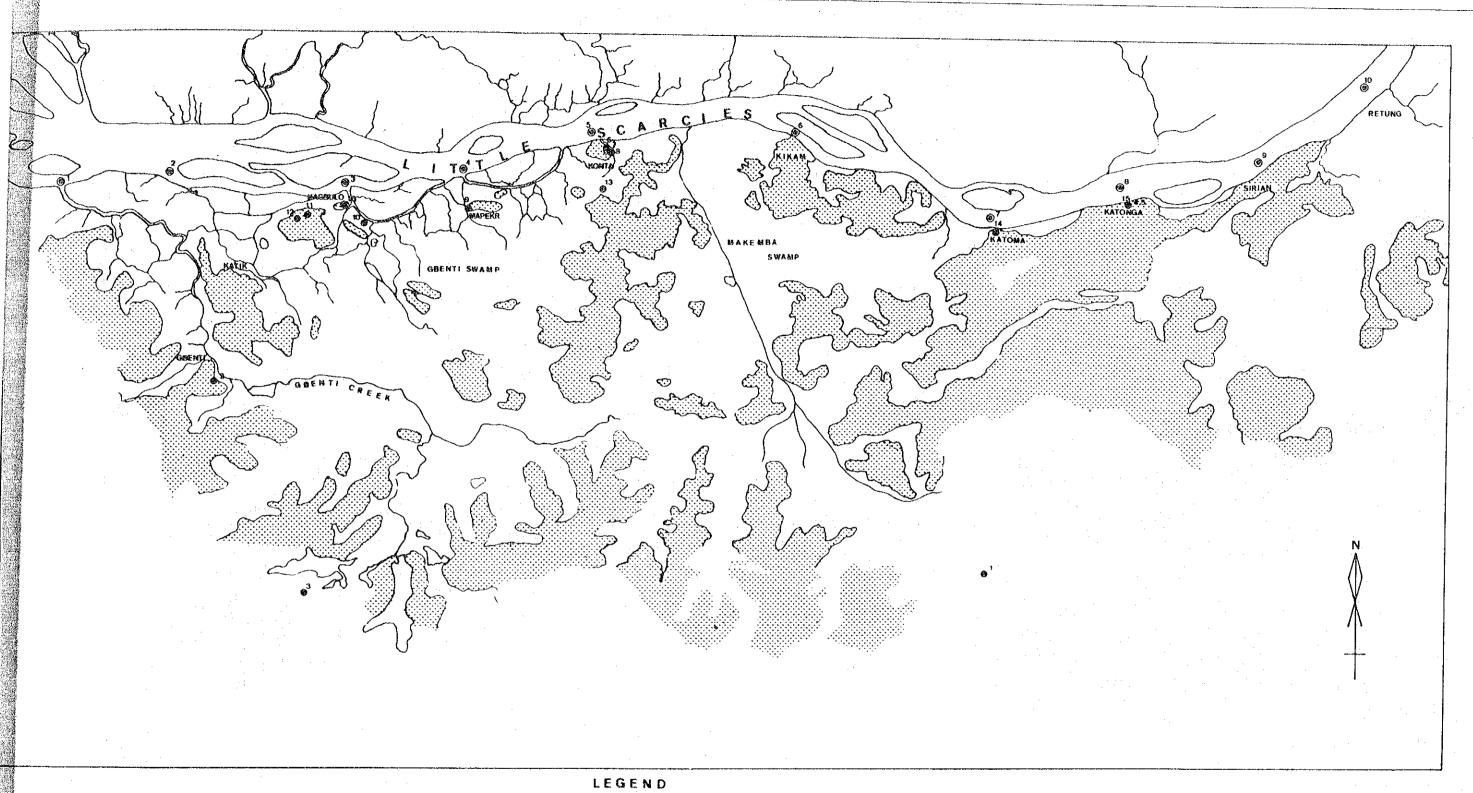

3-4-1 Groundwater usage

Every well is a hand-dug type that is commonly used in villages. The depth of wells ranges from 1.5 m to 5.4 m. The diameter varies from 0.8 m to 3.0 m, but many wells are around one meter in diameter.

People draw groundwater from these wells with buckets except for one well with a manual pump. The groundwater is used for domestic needs. There are few cases where the wells are used throughout the year; they are mostly used during the dry season.

3-4-2 Groundwater level and water quality

During the wet season, the groundwater level was usually shallow and varied from 0.2 m to 2.3 m below the ground

surface. In the dry season, the groundwater level ranged from 0.9 m to 3.2 m - a decrease ranging from 0.5 m to 1.2 m compared with the wet season.

In order to grasp the relationship between groundwater and the Little Scarcies river, a continuous groundwater level measurement was carried out every hour for three days in the wet season at Katonga. According to the results, the maximum daily fluctuation was about ten centimeters and there was no relation between groundwater and river water in the fluctuation. Further, the groundwater level was generally higher than the water level of the river. It is therefore considered that there is hardly any recharge from the river to the groundwater in the wet season.

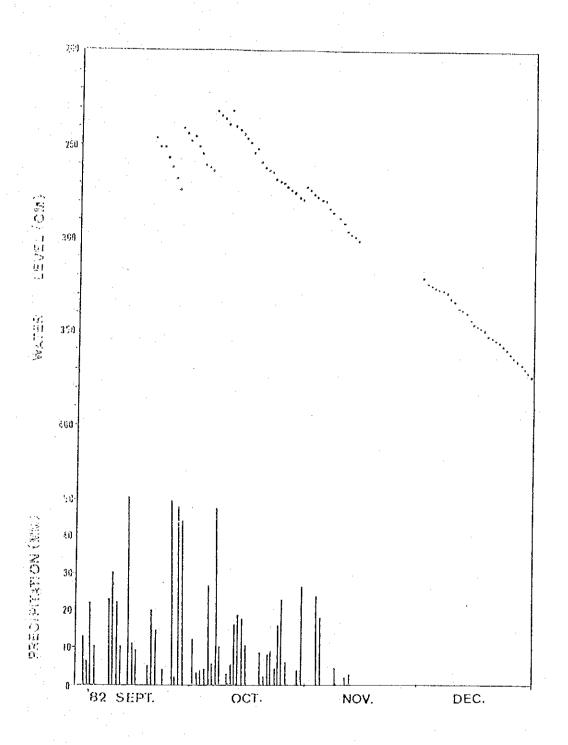

Another continuous groundwater level measurement was carried out once a day from Sept. 20th to Dec. 31st in 1982 at Kagbulo well. The result is shown in Fig. 3-4-2 and compared with precipitation at Rokpur. The groundwater level varies corresponding to fluctuation of the precipitation. After the wet season, the groundwater level drops linearly. Thus, it is estimated that the groundwater of the project area is mainly recharged from the precipitation.

The water temperature ranges from about 26.0°C to 28.5°C but is about 1°C lower in the dry season than the wet season. The pH varied from 4.4 to 6.4 and indicated strong acidity. Electrical conductivity ranged from 13.0 to 340 micr-mho per centimeter.

Some wells which exceeded 200 micro-mho per centimeter were probably contaminated by domestic sewage.

The water quality in the dry season is scarcely different from the wet season. While the water quality of the Little Scarcies and creeks were affected by the

Fig. 3-4-2 WATER LEVEL FLUCTUATION AT KAGBULO WELL

seawater intrusion in the dry season, the water quality of groundwater was hardly influenced by the seawater intrusion. The groundwater is therefore considered to be a stable water resource for irrigation use.

CHAPTER 4 METEOROLOGY AND HYDROLOGY

4-1 Meteorology

4-1-1 General

There are 7 meteorological stations and 4 pluviometrical stations in and around the Little Scarcies river basin, as listed upon Table 4-1-1. Their locations are also illustrated on Fig. 4-1-1.

The available meteorological data at these stations were collected, compiled and analysed. These data include air temperature, relative humidity, sunshine hours, winds, evaporation and precipitation. The period of records available in each station is summarized in Figs. 4-1-2 and 4-1-3.

The data from Lungi Airport meteorological station is considered to be more sustained. This station is located about 25 kilometers to the south-west of the study area and has more reliable climatic data and similar climatic conditions to the study area. Therefore, with these factors having been taken into consideration, the meteorological data obtained from this station, excluding rainfall, were used as the basis for the agronomic and irrigation studies.

At the Lungi station, records of air temperature, relative humidity, evaporation, sunshine hours and winds are available for the last 22 years. Extrapolation was necessary due to the occurence of missing data in a few months.

With respect to precipitation, the records at Rokupr station from 1951 to 1982 are directly referred to in this study, considering the results of the MRT Study on the correlation of rainfall among Rokupr, Lungi and Port Loko.

Daily data available LEGEND:

Daily data partly available Monchly data available

4-1-2 Air Temperature

The annual mean temperature at Lungi for the last 33 years is approximately 26.5°C and the monthly mean temperature shows little seasonal fluctuations. The variation between the highest and lowest monthly mean temperatures was about 3°C (Refer to Table 4-1-2 and Fig. 4-1-4). On the other hand, fluctuations of temperature within a day was relatively wide, or in the range of 4°C to 10°C.

Monthly mean maximum temperature is averaged at 30°C, while the mean monthly minimum temperature is 23°C.

4-1-3 Relative Humidity

The annual mean relative humidity at Lungi for the last 22 years is 82%. The relative humidity is high in the wet season and relatively low in the dry season. The seasonal fluctuation ranges from 75% in March to 89% in August (Refer to Table 4-1-3 and Fig. 4-1-4).

The mean relative humidity during 1963, and from 1970 to 1981 was estimated from the relative humidity obtained at 9:00 a.m. and 3:00 p.m. The longitude of the study area is 13°W and standard time in Sierra Leone is Greenwich Mean Time. Consequently between actual solar movement and local time in Sierra Leone, there is a lag of almost one hour. In view of this, the following formula is used and sufficient values are obtained.

RH mean = $(RH(9:00) \times 2 + RH(15:00))/3$

4-1-4 Sunshine Hours

At Lungi, the monthly sunshine hours averaged at 230 hours in the dry season and 140 hours in the wet

season. The annual sunshine hours were approximately 2,200 hours (Refer to Table 4-1-4 and Fig. 4-1-4).

According to the sunshine hours records the wet season seems to start and end earlier in recent years.

4-1-5 Winds

In Sierrra Leone the desert air or harmattan is normally experienced from December to February. However, the harmattan reaches the study area along the coast for short periods only.

The study area has predominant winds of West to Southwest direction. Monthly mean wind speed recorded at Lungi ranges from 2.1 meter per second to 3.2 meter per second. The annual mean wind speed is averaged at 2.6 meters per second (Refer to Table 4-1-5 and Fig. 4-1-4). The wind speed recorded at 9:00 a.m., in general, is smaller than those recorded at 3:00 p.m. and 9:00 p.m. each day.

The wind speed for the period from 1960 to 1969 is converted from the standard Beaufort classification. The wind speed for the period from January 1970 to May 1977 is estimated on the assumption that these records were taken at the height of 12.2 m above ground level.

4-1-6 Evaporation

The annual evaporation measured at Lungi for the period from 1960 to 1981 is averaged at about 1,400 mm, which corresponded to approximately 45% of the annual precipitation in the study area. The monthly evaporation ranges from 70 mm in August to 190 mm in March (Refer to Table 4-1-6 and Fig. 4-1-4).

4-1-7 Precipitation

The most important factors which affect the climate of West Africa are the dry, dusty harmattan or trade winds from the north, and the moist, cloudy monsoon from the south.

In winter the Sahara desert becomes comparatively cool and a high-pressure area develops, from which winds blow away. These dry Sahara winds blow southwards and are particularly dominant in the dry season.

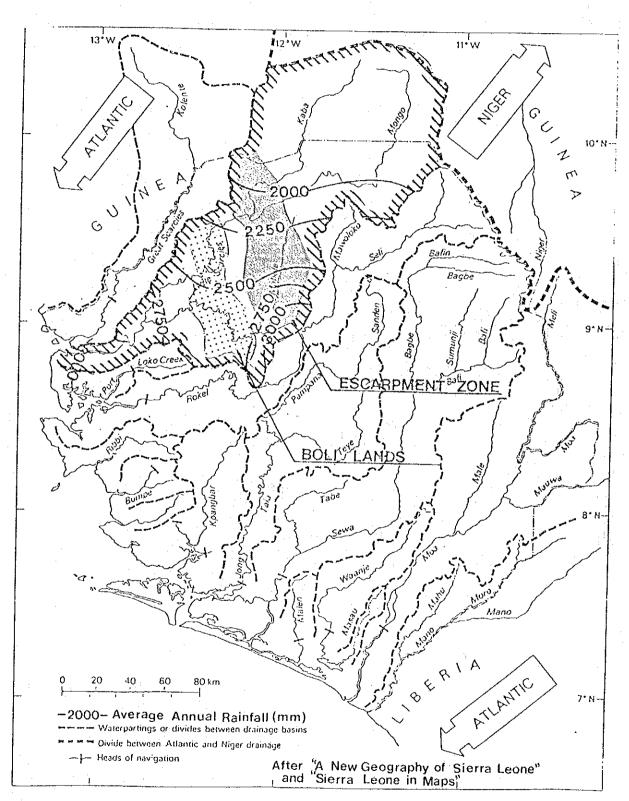

In summer the Sahara is very hot thus creating low pressure. The monsoon winds from the Equatorial and South Atlantic blow into West Africa and warm wet conditions prevail.

The rainfall of Sierra Leone is composed of two main elements. One is the convectional thunderstorm rains of the early and late wet season. These rains sometimes do not affect very large areas. Another is the steady monsoonal rains of the main wet season, roughly from mid-June to late September. In general, rainfall tends to decrease inland and northwards.

In the Little Scarcies river basin, rainfalls vary substantially by regions and from year to year. On the basis of available precipitation records, an isohyetal map of the upper Little Scarcies river basin has been prepared as illustrated on Fig. 4-1-5. The annual precipitation is less than 2,000 mm in the northern watershed which borders the upper Niger river basin, while it increases to more than 3,000 mm in the south-western coastal region. The average annual precipitation in the Little Scarcies river basin is estimated at about 2,400 mm as a whole.

According to the precipitation records at Rokupr from 1936 to 1982, the annual precipitation ranges from

Fig 4-1-5 ISOHYETAL MAP

2,128 mm to 3,618 mm. The annual mean precipitation is calculated at 2,960 mm. More than 95% of the annual precipitation is concentrated in the wet season from May to November. More than 60% of the annual precipitation (or about 1,810 mm) is concentrated in a period from July to September (Refer to Table 4-1-7 and Fig. 4-1-4). Number of rainy days (not less than 5 mm) averaged at 105 days a year (Refer to Table 4-1-8)

The consecutive three-day probable precipitation is estimated by Weibull plot method at 252 mm for the return period of 5 years, on the basis of the daily precipitation at Rokupr. (Refer to Fig. 4-1-6).

The monthly rainfall at main stations are shown in Fig. 4-1-7 and the fluctuation of annual rainfall is shown in Fig. 4-1-8.

4-2 Hydrology

4-2-1 General

The Little Scarcies river, which is one of the major rivers in Sierra Leone, originates in the Fouta Djallon Plateau in Guinea. It flows down from northeast to southwest as shown in Fig. 4-1-1. The highest peak of about 1,100 m in altitude is on the northern boundary, which lies between the Little Scarcies basin and the neighbouring upper Niger and Senegal river basins. The total length of the river is about 430 km and the average gradient of the upper portion is about 1/240 and lower portion 1/3,000. The catchment area of the Little Scarcies river is about 18,500 km² of which 5,500 km² are in the Republic of Guinea.

The catchment can be divided into three physiographic regions which run approximately north to south. They are the coastal plain, interior lowlands and interior plateau regions.

The coastal region is generally a low, level and swampy area extending some 30 km inland from the coast.

The coastal swamp is underlain by the Bullom series of marine and riverine sediments. Submergence was the cause of the drowned estuary and also the sand bar across the mouth of the river which has a ponding effect of fresh river water. Also tidal mangrove creeks are the result of the drowning of some river systems by sea water. According to the aerial photograph, a zone from Kotoma, Makemba North Swamp, Robis, Gbenti Creek to Gbenti Mouth is considered to be an old river course. The project area lies only a few metres above sea level and its soils are muddy in general.

The interior lowlands are approximately 80 km wide and the topography is that of an old peneplained

continental land mass. The western limit of this region is the rapids at Mange, where navigable water-The soils of this area way and tidal effect ends. are mainly reddish-brown lateritic soils, and the cover is secondary forest growth with scattered savannah. Most of the area is less than 150 metres above sea level and the ground is generally undulat-The rocks under the surface of this region are mostly granites and other crystalline rocks of the Precambrian to Cambrian periods. This region includes the flat treeless and seasonally swampy grasslands known as the bolilands, which is thought to be the site of a delta formed at a period of higher sea After debouching from the plateau valleys, the Little Scarcies river and its tributaries flow meandering over this alluvial deposit. Much of this area, including many old river channels, is flooded in the wet season but becomes quite dry in the dry season. The bolilands have many retarding basins.

The interior plateau region rises rapidly above the Interior Lowlands to a height of 300 to 600 metres. The scarp separating the two regions of the Interior lowland and plateau is developed along the western side of this region, particularly near Makeni. The number of inselbergs rises within this region near the border with the Republic of Guinea. The northern part of this region, which is mainly in the territory of Guinea, is another scarp or southern slope of the Fouta Djallon Plateau. The soil cover is secondary forest growth.

The area height relationship and area of each region of the Little Scarcies catchment are summarized in Table 4-2-1 and 4-2-2.

Table 4-2-1 AREA HEIGHT RELATIONSHIP

Contour Interval (m)	Area (km)	Percentage (%)
Over 600	1,500	8
300 - 600	6,100	33
75 - 300	5,100	28
0 - 75	5,800	31
Total	18,500	100

Table 4-2-2 AREA REGION RELATIONSHIP

Region	Area (km)	Percentage (%)
Coastal Plain	1,000	5
Interior Lowlands	4,800	26
Interior Plateau	12,700	69
Total	18,500	100

4-2-2 Available Data

Hydrological records available at some water level gauging stations on the Little Scarcies river are compiled and analyzed. The location of these stations and the period of water level recording are shown in Fig. 4-1-1 and Fig. 4-2-1 respectively. Discharge Measurement by the MRT team was conducted 12 times at the Robat gauging station in 1971 and 1972. However, it is reported that no discharge measurement has been carried out at any station since 1973.

Consequently on the Little Scarcies, there is only one available rating curve for the whole range of flows, which was prepared during the period from 1971 to 1972 at Robat. Rating curves for peak flows at Made, Sirian and Katoma were bullt up by the MRT consultants. The period of observation at each station is not sufficient for an accurate analysis. The Mange and Robat stations were monitored from 1972 until 1978, then they were closed down and the hydrological station transferred to Bantoro.

Water level records at the Mange station indicate tidal effect except at high river flow as shown in Fig. 4-2-2 and 4-2-3 and Table 4-2-3. At the Bantoro station, the water level drops below the 0 metre of the gauging staff in the low water season as shown in Fig. 4-2-2 and 4-2-4 and Table 4-2-3. The water level has been recorded at Mange and Bantoro by means of a staff reading, every one hour from 9 a.m. to 4 p.m. The water level at Robat was read weekly during 1971 and 1972, and observation was continued until 1978. However these records are said to have been mislaid as well as those at Made. The water level at the Mabole station, which is located on the Mabole river (one of main distributaries of the Little Scarcies), is shown in Table 4-2-3. Basic tidal information and the correlation between the Storey datum and the tide tables datum (the chart datum) are shown in Table 4-2-4.
