

4.1.4 Labor plan

(1) Culture schedule

1) Paddy

The culture schedule for paddy is as follows.

Monthly Works of Paddy Rice Culture and Management

| Works                  | Machinery        | Jan. | Feb. | Mar. | Apr. | May | Jun. | Jul. | Aug. | Sep. | Oct. | Nov. | Dec. |
|------------------------|------------------|------|------|------|------|-----|------|------|------|------|------|------|------|
| Plowing                | Disc plow        |      |      |      |      |     |      |      |      |      |      |      |      |
| Harrowing              | Disc harrow      |      |      |      |      |     |      |      |      |      |      |      |      |
| Land levelling         | Land leveller    |      |      |      |      |     |      |      |      |      |      |      |      |
| Fertilization, seeding | Tractor (seeder) |      |      |      |      |     |      |      |      |      |      |      |      |
| Ridging                | Ridger           |      |      |      |      |     |      |      |      |      |      |      |      |
| Top dressing           |                  |      |      |      |      |     |      |      |      |      |      |      |      |
| Weeding                | Aeroplane use    |      |      |      |      |     |      |      |      |      |      |      |      |
| Control                |                  |      |      |      |      |     |      |      |      |      |      |      |      |
| Water management       |                  |      |      |      |      |     |      |      |      |      |      |      |      |
| Harvesting             | Harvester        |      |      |      |      |     |      |      |      |      |      |      |      |
| Transportation         | Trailer          |      |      |      |      |     |      |      |      |      |      |      |      |

Plowing by disk plows is initiated in August, followed by three rounds of harrowing before land leveling which takes place in September and October. Then, fertilizing and sowing follows beginning in the middle of October to end in November. The three month period from September to November represents the most busy season of rice farming. Water management is maintained by means of man power from the end of sowing to February for about five months. Harvesting is executed by the combine, the harvest transported on trailers. Additional fertilizing, weeding and control of insect disease damage are all made by cropdusting techniques.

Table 4-1-5 presents the working hours of these operations for farming of different scales computed on the basis of the foregoing culture schedule.

Table 4-1-5 Working Hours of Wet Paddy Culture and Management

| Month | Jan.           |                | Feb.           |                | Mar.           |                | Apr.           |                | May            |                | Jun.           |                | Jul.           |                | Aug.           |                | Sep.           |                | Oct.           |                | Nov.           |                | Dec.           |                | Total          |                |

| 500   | -              | 2,000          | -              | 2,000          | 500<br>500     | 3,500          | 250<br>250     | 1,750          | -              | -              | -              | -              | -              | -              | 500            | 500            | 810            | 810            | 940            | 3,840          | 680            | 3,930          | -              | 2,000          | 750<br>3,680   | 20,330         |

Note: 1. Upper number of machinery column is using hours of combine, and the lower is of tractor.

2. Scale 50 ha Working hours with machinery (tractor) per ha 8.5 hrs.  
Working hours with human power per ha 42.5 hrs.

Scale 150 ha Working hours with machinery (tractor) per ha 8.6 hrs.  
Working hours with human power per ha 42.6 hrs.

Scale 500 ha Working hours with machinery (tractor) per ha 7.4 hrs.  
Working hours with human power per ha. 40.7 hrs.

3. Detail of estimation is accompanied by Appendix.

Use of the tractor reaches the highest peak in October when the operations of harrowing/land grading, land leveling and sowing overlap with themselves and the second highest peak in September and November. Plowing and harrowing/land grading in both August and September are achieved by the operator of a tractor alone without assistance, as might be inferred from the same values of tractor operating hours and manhour. During the October ~ November period when many operations overlap with themselves along with water management, which is executed by man power beginning at the end of sowing, the manhours reaches maximum. After this period, the only operation is water management in the next two months since additional fertilizing, weeding and control of insect disease damage by cropdusting is assigned to an outsider. Most of harvesting and transportation of harvest is performed in May and the rest (some one third of the workload) in April. Loading from the combine to the trailer requires assistants, which explains the large manhours in these months. In the schedules for 150-hectare (medium) and 500-hectare (large) scale farming, the tractor operating hours are 8.6 and 7.4 hours, respectively, and the manhours 42.6 and 40.7 hours, respectively, per hectare.

2) Soybean and wheat farming

The operation schedule of soybean and wheat farming is as follows.

Monthly Works of Soybean and Wheat Culture and Management

| Works                  | Machinery        | Jan.  | Feb.  | Mar.  | Apr.  | May   | Jun. | Jul. | Aug. | Sep.  | Oct.  | Nov.  | Dec.  |

| Harvesting             | Combine          |       |       | _____ | _____ |       |      |      |      | ..... |       |       |       |
| Transportation         | Trailer          |       |       | _____ | _____ |       |      |      |      | ..... |       |       |       |

Note: \_\_\_\_\_ Soybean, ..... Wheat.

The crop rotation of soybean as the export and wheat as the national staple food takes an ideal form in our project from the viewpoint of utilization of machinery and labor allocation; use of tractors is equal every month.

The farming of soybean is started in September, which is the harvesting month of wheat. The operation of plowing starts off following the harvesting of wheat to continue until it is October and November, the busy farming season of soybean farming. Since sowing is made in November, the work centered on the preparations such as subsoil breakup (once in four years) and harrowing/land grading. Then, intertillage and weeding and control of insect disease damage by means of the speed sprayer follow. March is the harvesting month for soybean.

The operation of plowing for wheat starts in April, followed by harrowing (a single round) then by fertilizing and sowing in May. No intertillage by cultivators is executed. In the period from June to August weeding and control of insect disease damage are undertaken by means of the speed sprayer and the month of harvest follows. The transportation of harvesting is completed before September ends.

Table 4-1-6 presents the monthly operation hours schedule of soybean-wheat crop rotation for different farming scales produced on the basis of the foregoing operation schedule.

The peak of tractor work in soybean cultivation is October and November, however, furthermore tractor is used for intertillage, weeding, control of insect disease damage, transportation etc. The peak of man power work is harvest season on March and next is November, however, the difference is few.

The operation of farming the wheat reaches the highest peak in May the seeding time of wheat. The tractor operating hours and manhours for this month can be equated with November when the culture of soybean arrives at its highest peak. The work of subsoil breaking is synchronized with the hours of planting the soybean. The total machine operating time and manhours of wheat culture are slightly less than those of soybean farming since no intertillage and weeding are performed in the former. The tractor operating hours and the manhours per hectare for

50-hectare (medium) scale and 150-hectare (large) scale farming are respectively as follows.

|                           |           | Total tractor<br>operating hours<br>per hectare<br>(in hours) | Total manhours<br>per hectare |
|---------------------------|-----------|---|-------------------------------|
| 50-ha<br>scale<br>farming | { wheat   | 9.5   | 14.0                          |
|                           | { soybean | 12.7  | 18.0                          |
|                           |           | } 22.2  | } 32.0                        |

As in the case of paddy culture, greater optimization in both the total mechanical operating hours and manhours is attained in the greater scales of farming. The manhours of soybean and wheat culture are respectively as 1/4 less as the manhours of paddy farming and there is marked evidence of labor saving in the former.

## (2) Study of labor demand and supply

### 1) Family labor hours

It is necessary to determine the standard supply (in hours) of family labor of a farmer in order to study how the demand of the monthly operating hours, as discussed in earlier Sections, is met by the supply of family labor.

The 1982 Censo Nacional de Poblacion y Vivienoas reports set the size of a family in the agricultural zones at six people on the average. Consideration of two persons (male and female of age) out of them as effective labor force draws up a monthly schedule of family labor as shown in Table 4-1-7.

In the area, rainfall occurs almost in the same number of days every month, so that the number of days suited for outdoor works does not vary much from month to month throughout the year. November which has the greatest rainfall than any other month of the year reduces the average working days by two. It follows, therefore, that there are extremely slight monthly fluctuations in the available family labor of a farmer.

### 2) Study of labor demand and supply

#### (i) Study of the supply of labor in the area

Since no determination has yet been made on the number of settlers and their family size in the area, it is impossible to estimate the amount of deficiency of supply against the demand of labor.

Table 4-1-7 Holding Labor Capacity

| Month | Working persons (laborers) | Work conversion persons | Working days per month | Actual working hours per day | Monthly holding labor capacity | Remarks |
|-------|----------------------------|-------------------------|------------------------|------------------------------|--------------------------------|---------|

- Note: 1. According to investigation 1982 of Censo Nacional de Poblacion Yvivienoas, a family in rural area consists of 6 persons. Therefore, it is supposed that working persons in a family are 2, and capable conversion is 1.0 for man and 0.8 for woman.
2. Working days per month is estimated by "Meteorological data of Yacyreta observatory, Meteorological Department, Ministry of National Defence.

Accordingly, the foregoing schedules of operating hours for paddy and soybean-wheat crop rotation farming are compared with the monthly supply of family labor force, as discussed earlier, and data are arranged to determine the balance of demand and supply of labor for each month as shown in Tables 4-1-8 and 4-1-9.

In paddy farming, family labor force can afford to supply the demand of 25-hectare scale except for the seeding period of October and November. In November, particularly, there is a labor shortage up to 101 hours or 15 employees when 101 hours is divided by unit manhours per day and this shortage must be covered by employment. The family labor force of a farmer cannot meet the demand of the 50 hectare scale farming in October, November and March when there is a shortage of labor force equivalent to 70 employees in total. In the case of a 100-hectare scale, the operation of August plowing only is achieved on family labor. In the period from September to April, about 330 employees must be employed. That is, the greater the forming area, the greater the labor shortage. We conclude by saying that the labor demand of 400-hectare paddy farming requires up to 2,000 employees during the cycle.

When farming of paddy is initiated on a large scale in the future, the area will have big labor problems.

In the case of soybean-wheat rotation farming, there is no serious labor shortage problem since the operating hours per hectare is no more than 1/4 of the hours required for paddy culture. As shown in Table 4-1-9, the labor demand of a 50-hectare farmer is fully met by the supply of family labor force without use of outside employers.

Note: Same to Table 4-1-8.

In the case of 100-hectare scale farming, the months of March, May, September and November demand respectively nearly 20 employees in employment, that is, a total of some 75 employees. However, the equivalent scale of paddy farming requires as five times as much or 330 employees. Although the size of labor shortage increases with increasing scale of farming in soybean-wheat crop rotation, the rate of increase is far less compared with paddy farming. It seems that the problem of labor shortage with soybean and wheat farming will not be serious.

(ii) Study of demand and supply of labor

It is apparent that there will be a shortage of labor in the area when the project is initiated. This will be a cause of great problems particularly among those new settlers who are going to manage farming on large scales. As already stated, since the number of new settlers as classified by the scales of farming in the area has not yet been known, it is impossible to determine the quantitative relation of demand and supply of labor there. Accordingly, estimation of this relation is made by studying the status of certain five villages and towns with similar conditions to determine the supply of labor available from both Itapua and Misiones Departments including these districts and comparing this supply with the prospected demand of labor arising in the area.

Tables 4-1-10 and 4-1-11 shows the labor force of these five villages and towns and Itapua and Misiones tabulated in the same style as Table 4-1-7. The prospected demand of labor in the area is computed on the assumption that the entire area, that is, the 79,880 hectare paddy farming Area B (planting occurring in half the total area in crop rotation with grazing ground) and 25,620 hectare soybean-wheat rotation Area A (excluding the 1,200 hectares of dairy complex), is managed on the 150-hectare farming scale.

The prospected demands of labor by this assumption are shown in Tables 4-1-12 and 4-1-13.

The demand of labor in the area (paddy and soybean-wheat farming combined) is estimated to amount to 2.2 million hours per year,

which is equivalent to 39% of the total labor force of the five villages and towns, i.e., 5.7 million hours. Further, as shown in Table 4-1-12, the demand of labor in the district in May, June, July and August is equal respectively to no more than 13% of the labor force of the five villages and towns. No definite forecast cannot be made of how much of labor these five villages and towns are able to supply, it seems reasonable to think that the area will find recruit in these months as rates of labor shortage are not so high. However, the remaining eight months suffer a high rate of shortage impossible to be covered by a supply of excess labor from the five villages and towns; the demands of labor in October and November, in particular, are each equivalent to 81% and 95% of the total labor force of the five villages and towns. Therefore, it is impossible to make a plan of labor supply to 5 towns and villages concerned.

Table 4-1-10 Labor Capacity Held by 5 Towns and Villages Concerned

| Month | Working persons | Work conversion persons | Working days per month | Actual working hours per day | Monthly holding labor capacity | Remarks |

| Dec.  | 3,750           | 3,390                   | 18.30                  | 7                            | 434,259                        |         |
| Total |                 |                         |                        |                              | 5,701,136                      |         |

Note: 1. Working persons are calculated by multiplying a population of 20,838 of rural area in a population of 5 towns and villages concerned (1982) of development area by employed population rate of Paraguay (40%, 1980) and Agriculture and stock farming population rate (45%).

$$\text{Working persons } 20,838 \text{ persons} \times 0.4 \times 0.45 = 3,750 \text{ persons}$$

2. Work conversion persons is estimated by multiplying 3,750 persons by sex ratio (men 52%, women 48%) and capable conversion (man 1.0, woman 0.8).

$$\begin{array}{l} \text{Formula } \left\{ \begin{array}{l} \text{Men : } 3,750 \text{ persons} \times 0.52 \times 1.0 = 1,950 \text{ persons} \\ \text{Women: } 3,750 \text{ persons} \times 0.48 \times 0.8 = 1,440 \text{ persons} \end{array} \right. \\ \text{Total} \qquad \qquad \qquad 3,390 \text{ persons} \end{array}$$

| Soybean-wheat rotation  |   |       |       |       |       |       |       |       |       |       |       |       |       |        |
| Upland<br>field area  | (hour)<br>Per farming body (a)              | 135   | 68    | 450   | 305   | 383   | 66    | 135   | 68    | 531   | 228   | 379   | 201   | 2,949  |
|   | (1,000 hours)<br>Per division (a) × 171 (2) | 23    | 12    | 77    | 52    | 66    | 11    | 23    | 12    | 91    | 39    | 64    | 34    | 504    |
| Paddy rice  |   |       |       |       |       |       |       |       |       |       |       |       |       |        |
| Paddy rice<br>field area  | (hour)<br>Per farming body (b)              | 600   | 600   | 945   | 630   | -     | -     | -     | 195   | 286   | 1,266 | 1,268 | 600   | 6,390  |
|   | (1,000 hours)<br>Per division (b) × 266 (3) | 160   | 160   | 251   | 168   | -     | -     | -     | 52    | 76    | 337   | 337   | 160   | 1,701  |
| (1,000 hours)<br>Areal total (2 + 3) (4)                                  |   | 183   | 172   | 328   | 220   | 66    | 11    | 23    | 64    | 167   | 376   | 401   | 194   | 2,205  |
| (4) / (1) (%)   |   | 3     | 3     | 6     | 4     | 1     | 0     | 0     | 1     | 3     | 7     | 8     | 4     | 3      |

Note: Same to Table 4-1-12. However, labor capacity held by departments for development is taken by Table 4-1-11.

As apparent from Table 4-1-13, the annual total of labor force (in hours) available in Itapua and Misiones is 68.66 million hours, only 3% of which, i.e., 2.2 million hours, is the total annual demand of labor force of the area. Moreover, the labor demand of the area for October and November is respectively 7% and 8% of the labor force of the equivalent months of Itapua and Misiones. It is high expected, therefore, that the demand of labor of the area will be fully supplied with extra labor from Itapua and Misiones. Accordingly, it is necessary to include both Itapua and Misiones in the labor project for the area.

(3) Study of the operating hours of machinery

1) The operating hours of machinery

The operating hours of machinery is determined, as follows, in order to study the relation of the operating hours to the actual operating hours of a machinery.

Workable Capacity per Machine

| Item \ Month                              | Jan.  | Feb.  | Mar.  | Apr.  | May   | Jun.  | Jul.  | Aug.  | Sep.  | Oct.  | Nov.  | Dec.  |
|---|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|-------|
| Working days per month (days)             | 20.50 | 19.15 | 19.20 | 20.45 | 21.10 | 20.95 | 22.20 | 20.65 | 20.55 | 19.45 | 17.75 | 18.30 |
| Actual working hours per day (hours)      | 7     | 7     | 7     | 7     | 7     | 7     | 7     | 7     | 7     | 7     | 7     | 7     |
| Monthly workable hours of machine (hours) | 144   | 134   | 134   | 143   | 148   | 147   | 155   | 145   | 144   | 136   | 124   | 128   |

Note: Working days is in accordance with Table 4-1-7.

The table given above computes the operating hours for a single piece of machine. The figures, of course, grow much greater when the number of machines increases as in large scale farming.

2) The operating ratio for machinery

The operating ratio for machinery is almost alike between

Table 4-1-14 Operation Conditions of Machinery in Paddy Rice Farming

Note: Upper number is combine, lower number is tractor.

different scales of farming and is calculated on a monthly basis for three different scales of paddy farming and two scales of soybean-wheat crop rotation farming in Tables 4-1-14 and 4-1-15.

(i) Paddy farming

As already stated in 4-1-3, the number of machines to be introduced and their horsepower are determined on the basis of the estimated workload for October and November when use of the tractors will reach peak. As is shown in Table 4-1-14, the operating ratio for this period is high regardless of the scale of farming.

This operating ratio for March and April is low because these months is the period for transporting harvested crop. There will be no plan for the use of tractors for the paddy growth period of December through February and the fallow period of May through June.

The combine has an extremely high rate of operation in March, the busiest season for harvest, while a low rate in April.

(ii) Soybean-wheat rotation farming

In soybean-wheat rotation farming, as shown in Table 4-1-15, use of tractors is equal throughout the year with an operating ratio of 50 ~ 55%, twice as high as that for paddy farming. This ratio is relatively low in February, June and July and high during the rest.

(iii) Summarization

The operating ratio for machinery has monthly fluctuations. In paddy-pasture farming patterns, tractors are not used at all for the total period of 6 months in the year. Utilization of the tractors during this periods would result in an increase in income, which would be particularly desirable for small scale farmers. However, there will be little chances for them to earn rent by loaning their unused tractors to neighbors within the area since the basic policy of the development project for this area is such that all settlers will own tractors and combines of their own.

The chances are to find borrowers of a tractor outside the area. This would make it necessary to study the farming patterns and their cycle of use of machinery of those neighboring area.

#### 4.1.5 Economics of farming

##### (1) Computation of non-farming income

It is expected that 25-hectare and 50-hectare paddy farmers alone will have leisure time to earn non-farming income. As already stated in connection with Table 4-1-8, a farmer on the scale of 100 hectares or more could not manage his own paddy farming within the limit of family labor alone and has to rely on employment. Moreover, 100-hectare farming requires assistance of up to three pieces of large machinery including a combine while 500-hectare farming 12 pieces of it. A large number of machines will have to be maintained and serviced during the fallow period of May through July. Computation of the estimated amount of non-farming income for them was made while taking into account Table 4-1-8 and the following conditions.

(a) It is assumed that 2/3 of the monthly leisure hours represents employment hours for non-farming income when leisure hours exceeds 1/2 of family labor hours in the month.

(b) It is assumed that no job is sought (hence no non-farming income) when leisure hours is smaller than 1/2 of family labor hours in the month.

(c) It is assumed that 20 days represents employment period for non-farming income for each of the three months of May through July of the fallow period.

(d) Female's employment time is equal to 1/2 of male's in either of the above (a) and (c).

##### 25-hectare paddy farming

o non-farming income during the fallow period (May to July)... condition ©

@1,000 Gs/day × 20 days/month × 3 months = 60,000 Gs

o non-farming income during the paddy growth period (Aug., Sept.,

December, January, February, April; six months)..... condition (a)

@1,000 Gs/day × 956 hours × 2/3 ÷ 7 hours/day = 91,000 Gs

60,000 + 91,000 = 151,000 Gs. Addition to this sum 1/2 of 151,000, the income from a female (his wife)'s employment gives an annual non-farming income of 226,000 Gs.

50-hectare paddy farming

o non-farming income during the fallow period (May to July)... condition (c)  
@1,000 Gs/day × 20 days/month × 3 months = 60,000 Gs

o non-farming income during the paddy growth period (Aug. and  
September; two months)  
@1,000 Gs/day × (359 hours × 2/3 ÷ 7 hours/day) ÷ 34,000 Gs

60,000 + 34,000 = 94,000 Gs. Addition to this sum 1/2 of 94,000 Gs,  
the income from a female (his wife)' employment gives an annual  
non-farming income of 141,000 Gs.

In addition, computation of the estimated amount of non-farming  
income for soybean-wheat rotation farming was made on the basis of  
Table 4-1-9. It is assumed that there is no non-farming income in the  
150-hectare scale farmers since they have only two months which fall  
in conditions (a).

25-hectare soybean-wheat rotation farming

o non-farming income during the crop growth period (January through  
December; 12 months) - Condition (a)  
@1,000 Gr/day × (2,315 hours × 2/3 ÷ 7 hours/day) = 220,000 Gs

Addition to this sum 1/2 of 220,000 Gs, the income from a female  
(his wife)' employment gives an annual non-farming income of 330,000  
Gs.

50-hectare soybean-wheat rotation farming

o non-farming income during crop growth period (January, February,  
April, June, July, August, September, December; 8 months)..condition (a)  
@1,000 Gs/day × (1,560 hours × 2/3 ÷ 7 hours/day) ÷ 150,000 Gs

Addition to this sum 1/2 of 150,000 Gs, the income from a female  
(his wife)' employment gives an annual non-farming income of 225,000 Gs.

100-hectare soybean-wheat rotation farming

o non-farming income during the crop growth period (January, February,  
June, July, August; five months)..... condition (a)  
@1,000 Gs/day × (910 hours × 2/3 ÷ 7 hours/day) ÷ 87,000 Gs

Addition to this sum 1/2 of 87,000 Gs, the income from a female  
(his wife)' employment gives an annual non-farming income of 130,000 Gs.

(2) Disposable income of the farmer

The disposable income of the farmer in the area is shown in Tables 4-1-16-(a) and 4-1-16-(b). The smallest scale of paddy farming (50 hectares; paddy 25 ha and pasture 25 ha) produces a disposable income of 1,184 thousand Gs. The smallest scale (25 hectares) and 50-hectare-scale of soybean-wheat rotation farming produce respectively a disposable income of 0.6 and 1.0 million Gs.

Table 4-1-16-(a) Disposable Income of Farmers...Paddy Rice --  
Pasture Rotation System

|                               |              | (1,000 GS) |       |        |        |        |        |        |
|-------------------------------|--------------|------------|-------|--------|--------|--------|--------|--------|

## 4.2 Distribution

As the survey area has natural conditions which are quite favorable for rice cultivation, there is a plan that in the future paddy fields of about 80,000 ha will be developed at the irrigable area in this district and a rice production increase of nearly 200,000 tons will be realized by the rotation system from paddy to other crops (1:1).

However, main foods in Paraguay are manjoca and bread, and the consumption of rice is still at a low level. The domestic demand for rice is sufficiently fulfilled by the domestic production. Furthermore, the excessive production, though not large, is being exported.

The trade volume of rice in the world is extremely small as compared with wheat and other farm products, representing only around 3% of the total production. Most of the trade market is occupied by Thailand and the United States of America. In this connection, we expected various difficulties concerning the marketability of rice which is to be produced in this area after the plan is carried out. Accordingly, we will examine in this chapter the outlook of the domestic demand and the possibility of exports.

In addition to rice, we will also examine various aspects of soybeans and wheat which are expected to be produced at the area of higher altitude in this survey area.

### 4.2.1 Rice

#### (1) Outline of production

According to the FAO statistics, the rice production in the world for 1980 totaled 397.60 million tons, accounting for 25% of the total grain production in the world of 1,561.00 million tons for the same year.

The growing area of rice in the world has somewhat changed annually in the last five years, which is shown in Table 4-2-1. However, the change is quite slight; from 143.10 million ha for 1976 to 143.50 million ha for 1980. Meanwhile, the rice production has generally grown; from 350.40 million tons for 1976 to 397.60 million tons for 1980, an increase of 13%.

By continent, the rice production on the Asian continent is

overwhelmingly high, registering 360.90 million tons for 1980, or as much as 91% of the worldwide production. On the Asian continent, the Chinese production is considerably dominant, registering 142.30 million tons for 1980, which is followed by 79.90 million tons of India. The combined rice production of the two countries represented 62% of the total rice production on the Asian continent for 1980.

The South American Continent ranks second, producing 14.40 million tons of rice for 1980, or accounting for 4% of the worldwide production. On this continent, Brazil, which has close relations with Paraguay, is the largest rice producer, producing 9.75 million tons for 1980, or representing 67% of the total rice production on the continent. The annual rice production of Argentina, which is also a neighboring country of Paraguay, is around 300,000 tons, accounting for only 2 ~ 3% of the total production on the continent.

The average growing area of rice in Paraguay for the last five years is about 30,000 ~ 38,000 ha, which is extremely small as a rice growing area on this continent. The production is also low; the highest in 1980 at 73,000 tons. The average production for the last five years is 63,000 tons.

During the last five years, the rice production of the South American continent or the above-mentioned two countries neighboring Paraguay has shown little increase.

As is shown in Table 4-2-2, the yield per unit area has seen a tendency for increase. The worldwide average increased by 13.1% from 2,448 kg/ha in 1976 to 2,770 kg/ha in 1980. By continent, the yield per unit area in Asia shows the highest increase of 13.6% from 2,480 kg/ha in 1976 to 2,818 kg/ha in 1980.

The increase rate of the yield per unit area on the South American continent is lower than the world average, showing only 9.5% from 1976 to 1980. In particular, the yield per unit area in Argentina, Brazil and Paraguay has seen little change for the last five years. Among these three countries, the rice cultivation in Argentina centers upon the paddy rice, which is conducted at irrigable areas. Accordingly, the yield per unit area is extremely high. On the contrary, in Brazil, the cultivation of the upland rice culture is mainly conducted, while the cultivation of paddy rice is limited in the southern states, centering on the State of

Source: FAO Production Yearbook

Rio Grande do Sul. The upland rice culture represents about 70% of the rice cultivation in Brazil. Under the circumstances, the production of paddy rice is at a level of 3,500 kg/ha but the yield per unit area for the rice grown in the upland rice is low. As a result, the national average of the yield per unit area is as low as around 1,500 kg/ha.

In Paraguay, the paddy field rice accounts for about 65% of the rice cultivation (on the basis of the areal comparison between paddy rice and upland rice culture for the last five years). Itapua department and Misiones department, which are to be covered by the current plan, play the central role. In 1979, the two departments represented about 70% of the growing area for the paddy rice. The yield per unit area of paddy rice, including that in the two departments, is around 2,300 kg/ha, but the national average of rice production is around 2,000 kg/ha, as is shown in Table 4-2-2.

## (2) Trade

Major rice producing countries of the Asian Continent, including China and India, have generally a large population and the rice produced there is almost consumed domestically. As a result, the trade volume of rice in the world is extremely small. As is shown in Table 4-2-3, the worldwide rice exports for 1980 registered 12.70 million tons, representing only 3% of the global production of 397.60 million tons. The export ratio is much lower than 22% for wheat for the same year. However, the rice exports in the world have gradually increased year after year; from 8.99 million tons for 1976 to 12.70 million tons for 1980, an increase of 41%.

As for the South American Continent, the rice exports have shown little change in the last five years partly because of the slow production rise. In 1980, the exports from South America represented only 4% of the total exports in the world. In particular, the exports from Brazil have dropped sharply since 1978 when the country suffered a production drop caused by the drought damage. Paraguay has been exporting, though the volume is very small.

As for the imports, the rice imports to the Asian continent which has an overwhelmingly large production are also the highest since such countries on the continent as Indonesia, Iran, Iraq and Saudi Arabia have

been suffering a rice shortage. As is shown in Table 4-2-4, the Asian Continent imported 7.60 million tons of rice in 1980, accounting for 54% of the worldwide imports of 12.70 million tons. It is followed by 18% for the African Continent and 12% for the European continent.

The rice imports to the South American continent were at a low level of 100,000 tons in the past. In 1978, however, the imports to Brazil rose sharply because of the production drop caused by the drought damage. As a result, the imports to the continent for 1979 jumped to 920,000 tons, and, in 1980, also reached 570,000 tons. In Paraguay, the per capita consumption is small and they are self-sufficient in rice. In recent years, the country has not imported rice, except for the drought damage year of 1978.

(3) Study of marketability in connection with rice production increase at the survey area

As mentioned earlier, the volume of the rice trade in the world is extremely small, representing only around 3% of the worldwide production. The major importers are the countries in Asia, Africa and Europe.

The rice imports to South American countries are at an extremely low level, as is seen in Table 4-2-4, except for 1979 and 1980 in Brazil.

Argentina is one of a few nations, except for Asia, which have an excessive power to export rice. As is shown in Table 4-2-5, the country has been exporting rice to many nations, though the volume is small. The volume of the rice imported from Argentina ranges from about 1,000 tons to about 10,000 tons. The annual average of the rice exports from the country for the last five years is about 100,000 tons.

Paraguay has also been exporting rice, though the volume is small. (See Table 4-2-6) Its stable market is Chile. The Paraguayan rice is transported by land to Resistencia in Argentina, and then to Chile by train. The exports are also made to Europe and other regions, which are not stable markets.

Under the circumstances, many problems are expected for the marketability of the rice which will be produced in a larger volume than ever because of the construction of the Yacyreta dam. In this connection, we will examine the domestic demand in Paraguay and the situation in Brazil which has been importing rice for the last few years.

## 1) Domestic Demand

As was already mentioned in 2.9, the per capita rice consumption in Paraguay still sees a tendency for a slight increase, although the increase has somewhat slowed down. The per capita consumption for the last five years averaged 21.2 kg per annum for the unhulled rice (13.8 kg per annum in terms of brown rice). If the increase in the per capita consumption is not taken into account and the future demand for rice in Paraguay is calculated only on the basis of the population increase, the following Table will be obtained.

| Item<br>Year | Per capita<br>consumption<br>(kg per annum) | Population<br>forecast<br>(in 1,000) | Consumption<br>(1,000 tons) | Increase from the<br>present level<br>(1,000 tons) |
|--------------|---|--------------------------------------|-----------------------------|--|
| Present      | 21.2  | -                                    | 63                          | -  |
| 1990         | 21.2  | 4,231                                | 90                          | 27   |
| 2000         | 21.2  | 5,405                                | 115                         | 52   |

- Note: 1. For the "present" column, the average for the last five years.
2. Per capita consumption is indicated in terms of the unhulled rice.
3. Population forecast is made on the basis of the materials supplied by MAG.

This Table indicates that the requirement for rice to be caused by the population increase will be about 52,000 tons for the year of 2000. As the yield per unit area has not increased now, this requirement should be fulfilled through an increase in the planted area.

## 2) Rice in Brazil

As was mentioned earlier, Brazil is the largest rice producing nation on the South American Continent, and was also a rice exporting nation, though it imported some rice in 1972 and 1975. However, Brazil has become a rice importing nation since 1978 when it was hit by a drought damage.

In the south region of Brazil, a stable production of paddy rice is being made with irrigation facilities, while in the central high-land region and north and north-east region most of the rice cultivation is for the upland rice, which means that a stable production is unlikely

because this type of production depends heavily on weather.

(See Table 4-2-7 and Fig. 4-2-1) In addition, the Brazilian Government has introduced a minimum price guarantee system for 42 kinds of farm products, including rice, in order to protect producers and maintain the domestic supply-demand balance. The price of respective farm products is determined by the CFP before the start of planting. This mechanism plays an important role that "farmers should analyze respective prices and choose the most advantageous product for the specific year." Accordingly, the farm products a farmer produces generally change year after year; in other words, the upland rice is not always produced for the same area every year. If the prices of soybeans and kidney beans, which are major farm products in Brazil, are higher, the land area for the upland rice is easily used for those products.

Under the circumstances, not only the production of the upland rice depends upon weather, but also the planted area varies year after year, which leads inevitably to an unstable rice production.

As is shown in Table 4-2-8 and Fig. 4-2-2, Brazil has become a importing nation since 1978 when it suffered a drought damage, and partly because of the population increase. For 1983, the country also experienced a trade deficit and is in danger of a permanent shortage of rice. This is closely related to the serious political problems which the country now is faced with.

In the 1970's Brazil maintained an extremely high economic growth thanks to foreign aids of funds: an average of 11% between 1968 and 1973, and 6.5% even after the first oil crisis between 1974 and 1980. Meanwhile, the country's cumulate foreign debts rose sharply, reaching \$83.6 billion in 1982. At the end of 1982, Brazil came to a stalemate of the foreign debts, and called on the IMF to take relief measures. This has caused a fundamental change of the economic policy, which is still under way. There is no doubt that the problem of the foreign debts will take a long time to be settled. In addition, the country has a large amount of internal debts (\$29.0 billion as of November, 1983). The Government has to work out the future policy under various restrictions caused by those foreign and internal debts. In examining the rice shortage, we must take these political problems into considerations.

Table 4-2-7 Yearly Production of Unhulled Rice in Brazil

| Year    | Planted area (ha) | Production volume (t) | Yield per unit area (t/ha) | Remarks |
|---------|-------------------|-----------------------|----------------------------|---------|
| 1970    | 4,979,165         | 7,553,083             | 1,517                      |         |

Fig. 4-2-1 Brazilian Rice (Unhulled rice) Production (by year)

On the basis of the present situation of the rice production and the policy in Brazil which have been analyzed so far, we will discuss the future of rice production in Brazil.

(i) Demand Increase to Be Caused by Population Increase

The population of Brazil increased at an average rate of 2.49% between 1972 and 1983. This rate is unlikely to change suddenly.

If this rate of increase is unchanged in the future, the population is projected to increase from 128.20 million in 1983 to 164.00 million 10 years later or in 1993. In other words, the population increase during the period is expected to reach 36.00 million.

(See Table 4-2-9) The per capita rice consumption per annum (for the unhulled rice) averaged at 74.6 kg for the last 13 years. (See Table 4-2-10) Therefore, even if the per capita consumption does not increase, the demand for rice will increase about 2,700,000 tons 10 years later.

$$74.6 \text{ kg/person/year} \times 36.00 \text{ million} = 2,700,000 \text{ tons}$$

It is quite unlikely that, in Brazil where the emphasis is placed on the production of upland rice, an increase in the yield per unit area will be made in order to cope with the above-mentioned demand increase. Accordingly, the planted area should be expanded to cope with the demand increase. However, it is difficult to develop new areas for paddy fields because of the financial problems. Development of paddy fields requires more expenditures as well as more time. As a result, more upland rice should be produced despite the low productivity.

As is shown in Table 4-2-7, the rice yield per unit area in Brazil is about 1,480 kg/ha. However, excluding the States of Rio Grande do Sul and Santa Catarina in the southern Brazil where the production at paddy fields is mainly conducted, the yield per unit area for upland rice is estimated to average around 1,300 kg/ha. Therefore, to make up for the demand increase of 2,700,000 tons, the planted area should be increased by 2.00 million ha ( $\approx 2,700,000 \text{ tons}/1,300 \text{ kg}$ ).

The existing planted area totals about 6.00 million ha. It is extremely difficult to increase the planted area corresponding to

| Average | -                                 | -  | -  | -   | -                    | 74.6                             |         |

Note: (-); trade surplus, (+); trade deficit.

one-third of the existing area and then continue an increase in the planted area of more than 200,000 ha every year.

(ii) Specialization of farm products

Because of the foreign debts, Brazil now has to realize a trade surplus. In this connection, the Government is required to produce the farm products which have high marketability overseas. At present, soybeans and corns are possible farm products to be exported, since these quotations are clear in the international market. Therefore, it is apparent that these products will be increasingly specialized in the future. On the other hand, the Government will be unable to introduce a policy emphasizing the rice production. In fact, it is expected that from 1983 to 1984 the planted area for rice will decrease, while that for soybeans and corns will rise.

(iii) Fund shortage in the fiscal policy

In order to increase rice production by the expansion of the planted area, the investments are required for the consolidation of the infrastructure. In particular, it is evident that a large amount of investments are required for the development of paddy fields with irrigation facilities.

It is doubtful that the Government suffering from both foreign and internal debts should spend money for such investments. The Government has difficulties in extending agricultural loans because of the fund shortage. Meanwhile, producers will also find it difficult to carry out the farm management by such loans under a high inflation.

The scale and contents of the 1984 budget of the Federal Government are yet to be seen. We now analyze the draft budget of the State of Sao Paulo for fiscal 1984.

The budget scale is 4,000 billion Crs. down 37% from 1982 in real terms. The investments did not reach 2% of the total budget, registering only 77 billion Crs. or down 76% from 1982 in real terms. This apparently indicates that, even though the State Government of Sao Paulo is willing for consolidation of the infrastructure for agriculture, the possibility of realization is quite dim from the viewpoint of funds. This budget is computed on the premises that the inflation rate for

1983 is 200% and that for 1984 is 87%. If the inflation rate for 1984 is not confined within the projection, the investments will further drop.

Meanwhile, the Federal Government is obliged to see no deficit in public spendings. It is quite probable that its fiscal position will also be extremely difficult like that of the Sao Paulo State. If these negative factors of investment shortage emerge with some time lag, we will not be able to make an optimistic forecast concerning the rice production 10 years later.

(iv) Summary

On the basis of our above-mentioned study of the present situation and future outlook of the rice production in Brazil, it can be summarized as follows:

- a. The demand for rice is certain to increase.
- b. It is doubtful that the domestic production could meet the demand increase.

3) Summary of marketability

We have studied the domestic demand for rice in Paraguay and the long-term outlook in Brazil. We now can say, concerning about 200,000 tons of rice to be produced at the survey area, that, if 40,000 tons, which is to be consumed domestically in Paraguay because of the population increase, is deducted, the remaining 160,000 tons should be placed on the foreign market. The volume is about half of the demand increase projected 270,000 tons per year in Brazil.

As mentioned earlier, the rice production in Brazil has many difficulties. Brazil is expected to continue the rice imports, and is very likely to import rice from Paraguay. However, if the Brazilian Government steps up the rice production by effectively making use of the present minimum price guarantee system, the situation will not necessarily be optimistic in view of the potential resources. The possibility of marketability should be examined further for Europe and Africa.

Next, the selling price of rice to be produced at the survey area can be calculated as follows.

The price is \$205/t on delivery at Stroessner (for Brazil) and

\$225/t on delivery at Paranagua Port (for Europe). As is shown in Table 4-2-11, the average price per ton for the last five years (1977 ~ 1981) is \$378 in Bangkok and \$277 in Argentina (1976 ~ 1980). The prices in Bangkok and Argentina include the export tax and can not simply be compared with the above-mentioned selling price. However, the price of rice to be produced at the area will be substantially competitive in the overseas market.

The following selling price is calculated on the basis of the per unit production cost for the farming pattern determined for this survey.

(1) Study of selling price

a. Production cost ..... \$175/t

The production cost per kilogram is 22.6 Gs (for the farmer with managing scale of 150 ha). When it is computed into dollar (\$1 = 160 Gs) the cost is \$145/t ( $\div 22,600 \text{ Gs/t} \div 160 \text{ Gs}$ ). If the profit, etc. are set at 20%,

$$\text{\$145/t} \times 1.2 \div \text{\$175/t}$$

b. Storage fee ..... \$7/t

The storage period varies. In this estimate, the period is set at three months. The storage fee of M.A.G. is 350 Gs/t/month.

Therefore,

$$350 \text{ Gs} \div 160 \text{ Gs/\$} \times 3 \text{ mo.} \div \text{\$7/t}$$

c. Transportation

Delivery at Stroessner City ..... \$23/t

Delivery at Paranagua Port ..... \$40/t

Delivery at Stroessner City

(a) The distance for transportation from the district to Stroessner City is 300 km.

(b) The average of transportation fee is 1.2 Gs/kg per 100 km (according to M.A.G.).

Therefore, the transportation fee is:

$$1,200 \text{ Gs/t} \div 160 \text{ Gs/\$} \times 3 \div \text{\$23/t}$$

Delivery at Paranagua Port

(a) The transportation route is the district - Stroessner - Paranagua Port.

Source: FAO Trade Yearbook

The distance from the area to Stroessner is 300 km.

The distance from Stroessner to Paranagua Port is 800 km.

(b) The average transportation fee in Brazil is 20 Crs/t/km.

When the transportation fee between Stroessner and Paranagua Port is computed at the exchange rate of 900 Crs/\$,

$$20 \text{ Crs/t/km} \div 900 \text{ Crs/\$} \times 800 \text{ km} \doteq \$18/\text{t}$$

(c) When the transportation fee within Paraguay is added, the total transportation fee will be \$40/t.

d. Selling price

On the basis of the above-mentioned calculations, the following selling prices will be obtained.

Delivery at Stroessner (for Brazil) ..... \$205/t  
(\$175/t + \$7/t + \$23/t)

Delivery at Paranagua Port (for Europe) ..... \$225/t  
(\$175/t + \$7/t + \$23/t + \$18/t)

(ii) Rice import by continent

The rice of Paraguay is expected to be exported to Europe and Africa, in addition to Brazil.

The European continent as a whole imported 1,600,000 tons of rice for 1980. Major importers were France (253,000 tons), the Netherlands (193,000 tons), Belgium (176,000 tons), West Germany and Italy. Paraguay once exported rice to France and the Netherlands. Meanwhile, the African continent as a whole imported 2,350,000 tons of rice for 1980. Major importers were Nigeria (387,000 tons), Senegal (275,000 tons), South Africa (126,000 tons), Madagascar (161,000 tons) and Ivory Coast (230,000 tons).

While European nations generally want high-quality rice, it is said that African nations seek lower-priced rice, even though the quality is low. Rice dealers in Asuncion have already made contact with these countries, which are expected to become the importer of the Paraguayan rice.

#### 4.2.2 Soybean

##### (1) Outline of production

As the demand of feed and edible oil grows in the world market in the 1970s, soybean production shows a remarkable increase. As shown in Table 4-2-12, the total growing area of soybeans in the world increased by 16% from 44.6 million ha in 1976 to 51.8 million ha in 1980. At the same time the production of soybeans increased by 28% from 63.1 million t in 1976 to 80.9 million t in 1980 in the world.

In viewing production by continent, North and Central America including the United States, top producer of the world is ranked first. In 1980 North and Central America produced 49.8 million t of soybeans which occupied 62% of the total production in the world (80.9 million). South America having shown a remarkable growth is ranked second having produced 19.5 million t in 1980 which exceeds 10.0 million t in Asia.

Such districts of South America Continent as the Middle Western part of Brazil, Central part of Argentina and Eastern part of Paraguay are blessed with the natural conditions for soybean culture and, therefore, the production has remarkably grown in those districts as the world demand is expanded. In comparison with 1976 the production of soybeans in 1980 are increased by 500% in Argentina, 140% in Brazil and 200% in Paraguay. Production increase in such countries is respectively attributable to the increase of planted area and, as indicated in Table 4-2-13, the yield per unit area respectively shows a decline except Argentina in the last 5 years. The yield per unit area of North and Central America is generally high and they are ranked first in producing soybeans as the area is increased.

##### (2) Foreign trade

While the demand of soybeans will be increasing from now on, most of the producing countries are in the position of self-supporting at best or, what is more, of lacking in the soybeans for domestic use. China, which used to be a top producing country of soybeans, is converting to a importing country of soybeans.

At the present time the supplying countries are in North and Central America and South America. In 1980 these Continents exported the soybeans

Source: FAO Production yearbook

equivalent to 98% of total amount of exported soybeans (26.9 million t). Only the United States occupied the share of 81% of total amount (Refer Table 4-2-14). Those soybeans are exported mainly to the European and Asian countries. Compared with 27.0 million t imported in the world market, Europe imported 16.8 million t and Asia imported 7.3 million t. These figures are equivalent to 62% and 27% of the total amount imported (Table 4-2-15). Japan and such European countries as West Germany, Holland, Spain are major importing countries of soybeans and in those countries imported soybeans are utilized as materials of processed goods like soybean oil. The surplus exceeding the domestic consumption is exported in bulk from Europe.

With regards to the export of soybeans (cake and flour) as shown in Table 4-2-16, North · Central America exported 7.1 million t and South America exported 7.0 million t in 1980. They respectively occupied 40% and 39% of the total amount of exported soybeans (cake and flour) in the same year. In both of the Continents soybeans are exported mostly from the United States and Brazil. As shown in Table 4-2-18, Europe is ranked first in exporting soybeans (oil) with the amount of 1.2 million which is equivalent to 38% of the total amount of exported soybeans (oil). Europe is followed by North · Central America and South America. As pointed out before, the materials of edible oil exported from Europe are mostly the soybeans imported from the United States and Brazil.

Thus, soybeans are dealt with, taking to pieces such as beans, husks, flour and oil. In the United States it is exported in the form of beans. 21.8 million t of soybeans, which are exported from the States in 1980, are equal to 45% of the total production (48.8 million t) in the United States. On the contrary 1.5 million t of exported soybeans occupied 10% of the total amount of production (15.2 million t) in Brazil in the same year because the rate of processed goods is high.

It is considered that oil expressing capacity per annum amounts to 22.0 million t in Brazil. Since 15.2 million t were produced in the peak year of 1980, the surplus of capacity is considerably available even if 10% is occupied by cotton-seed oil and peanut oil. In order to make the best use of these facilities, Brazil imports the soybeans from the neighboring countries such as Paraguay, Argentina and the United States

though Brazil is regarded as a big producing country of soybeans. By using the surplus of facilities, Brazil produces soybeans (oil and cake) and exports them finally. The Government of Brazil has set up "Draw back" system which enables the importers of soybeans to import free of tax on the assumption that they must be exported again. Owing to such incentives the soybeans exported from Brazil are decreasing.

(3) Study of Marketability Concerning the Production of Soybeans Being Increased in the Survey Area

As a domestic demand of edible oil is limited in Paraguay, oil expressing factories are small in production scale and the export of processed goods is very scarce. Soybeans have conventionally been exported in unprocessed form to Europe as shown in Table 4-2-20. At present, however, soybeans are only exported in unprocessed form to Brazil. There is nothing to worry about the marketability of soybeans in Paraguay because she is blessed with favourable geographical conditions.

The selling price (in the City of Stroessner) of soybeans produced in the survey area is computed \$199 as follows. As the above price has fallen short of the recent average price/t, \$204 (1978 ~ 1982) as shown in Table 4-2-20, and also the average price of soybeans imported from Paraguay to Brazil, \$229.9 in 1982, it will be a competitive price even in the future.

- 1) Farmer's price ..... \$169/t
  - If the production cost of 24,600 Gs/t (farmer operating 150 ha) is converted with 160 Gs/\$,
 
$$24,600 \text{ Gs/t} \div 160 \text{ Gs} = \$154$$
  - Profit of 10% is added
 
$$\$154 \times 1.1 = \$169$$
- 2) Storage fee ..... \$7/t
  - On the assumption that duration of storage is 3 months the computation is made with the storage fee of 350 Gs/t/month (M.A.G. data) as mentioned under.
 
$$350 \text{ Gs/t/month} \div 160 \text{ Gs/\$} \times 3 \text{ (month)} \div \$7/t$$
- 3) Transportation cost ..... \$23/t
  - a. Transporting distance is 300 km from the district to the city of

Stroessner.

b. As the average transportation cost is 1.2 Gs/kg per 100 m, \$/t is as follows.

$$1,200 \text{ Gs/t} \div 160 \text{ Gs/R} = \$7.5/\text{t}/100 \text{ km}$$

c. Total transportation cost

$$\$7.5/\text{t} \times 3 = \$23/\text{t}$$

4) Total

$$( 1 + 2 + 3 ) \dots\dots\dots \$199$$

It is considered that the transportation cost of soybeans in Paraguay will become lower due to the completion of "Paranagua Export Corridor Plan" already discussed in Chapter 2. 2.9.2. Therefore, soybeans production will necessarily become much more profitable than ever in Paraguay.

(Note) This table is made of Table 4-2-20 ① and 4-2-20 ②.

#### 4.2.3 Wheat

##### (1) Outline of production

Wheat production of the world amounted to 444.6 million t in 1980 which occupied 28% of the total production of cereals in the world (1,561.0 million t). Asia is ranked first in the production, followed by U.S.S.R., Europe, North Central America. In 1980 the wheat production of these Continents occupied 93% of the total production in the world.

The recent amount of wheat exported in the world is approximately 90.0 million t which is mainly exported from the United States, Canada, Australia, France and Argentina.

In South America Argentina is the top wheat producing country blessed with favourable natural conditions. In 1980 the production of Argentina was 7.8 million t which occupied 65% of the total production (12.0 million t) of South America. It was followed by Brazil. As shown in Table 4-2-21, South America as a whole imports the wheat from the other Continents as the demand can not be met with production in South America.

##### (2) Wheat in Paraguay

Paraguay imports more than 50% of the domestic demand every year as already discussed in 2-9-3. In recent years wheat has been imported mostly from Argentina as shown in Table 4-2-22.

In 1981 the total value of wheat imported including processed goods amounted to \$13.87 million (FOB) which occupied 43% of the total value of food imported (\$32.6 million). The total value of foods imported is equivalent to about 6% of the grand total value of Paraguayan imports (\$506.11 million). Due to an encouraging policy of wheat production such as the promotion of mechanization by the National Wheat Plan, wheat production has been remarkably increased in recent years. However, the production has not yet reached the level where the domestic demand can be met.

Under such circumstances the production increase of wheat is of great importance to Paraguay. There is nothing to worry about the marketability of wheat produced in the survey area.

CHAPTER 5  
LAND IMPROVEMENT PLAN

## 5.1 Irrigation Plan

### 5.1.1 Basic policy for irrigation plan

The project area is divided into Area A and Area B by the Land Use Plan and it was decided to cultivate upland crops such as wheat, soybeans, etc., in the Area A and to cultivate paddy in the Area B. In order to secure a stabilized production of crops when observing from the conditions of location, it is considered that irrigation to paddy is necessary in the Area B.

The water source of this irrigation plan is the Yacyreta Dam. The intake of irrigation water is naturally performed from the intake work provided on the above-mentioned dam and is conveyed and distributed to the project area. The water-intake altitude shall be the normal full water level of 82.0 m of the Yacyreta Dam and as a rule, the irrigation area shall be the range that can be irrigated by the natural flow from distribution canals. However, water-distribution by partial pump usage will also be planned. The formulation of outline of the irrigation plan for this year shall be based on the abovementioned basic policy and shall be executed upon sufficiently studying the following items.

- (1) The irrigated area for this year's plan shall be Area B which occupies the principal part of the project area.
- (2) The objective crop shall be paddy which is the main crop of Area B and settings on the benefited area and actual irrigated area shall be made based on the topographic conditions, the Cultivation Plan, etc.
- (3) The maintenance or abolition of forests within the benefited area shall be based on the Environmental Conservation Plan and the forest area to be preserved shall be excluded from the irrigated area.
- (4) Residential areas, facility sites, slight uplands, small-scaled forests, etc., within the benefited area shall be excluded from the irrigated area and the area percentage excluded shall be 20% of the benefited area.
- (5) The irrigation system and irrigation block shall be decided based on the existing roads and rivers and the newly planned system of irrigation canals, drainage canals and roads.

(6) As a rule, the irrigation canal shall be of the open canal system by natural flow and shall be passed through a high part to extents possible.

(7) The route selection of the irrigation canal shall be performed by utilizing a topographic map of 1/50,000 scale.

(8) Areas in which the use of pumps can be considered economical shall be made irrigation areas to be irrigated by pump lift.

(9) With the exception of accessory structures, the irrigation canal shall be an unlined canal.

(10) The use of river waters flowing into the area from hinterland shall be appropriated for future redevelopments and the utilization plan shall be schemed in the following year upon awaiting the results of the presently performed observation.

#### 5.1.2 Irrigated area and principal facilities

The generally determined benefited area based on the basic policy becomes 99,850 ha, the irrigated area becomes 79,880 ha and the actual irrigated area becomes 39,940 ha. These areas are shown in Table 5-1-1.

Irrigation facilities are largely classified into the irrigation canal, aqueduct, diversion works, drop structures, regulating facilities of water level and pump stations and they become as shown in Table 5-1-2 when they are generally determined from the 1/50,000 scale topographic map, and the road and drainage canal system map. Detailed plans of drop structures, regulating facilities of water level and diversion works shall be in accordance with the following year's study. Moreover, it has been arranged under the Agreement between the countries of Paraguay and Argentine that the intake works shall be separately executed in the Yacyreta Dam works.

Furthermore, the designed irrigation system map which indicates the irrigation benefited area and the principal facilities is shown in Fig. 5-1-1 and the designed irrigation system flow chart is shown in Fig. 5-1-2.

Table 5-1-1 Land Use Plan in the Project Area

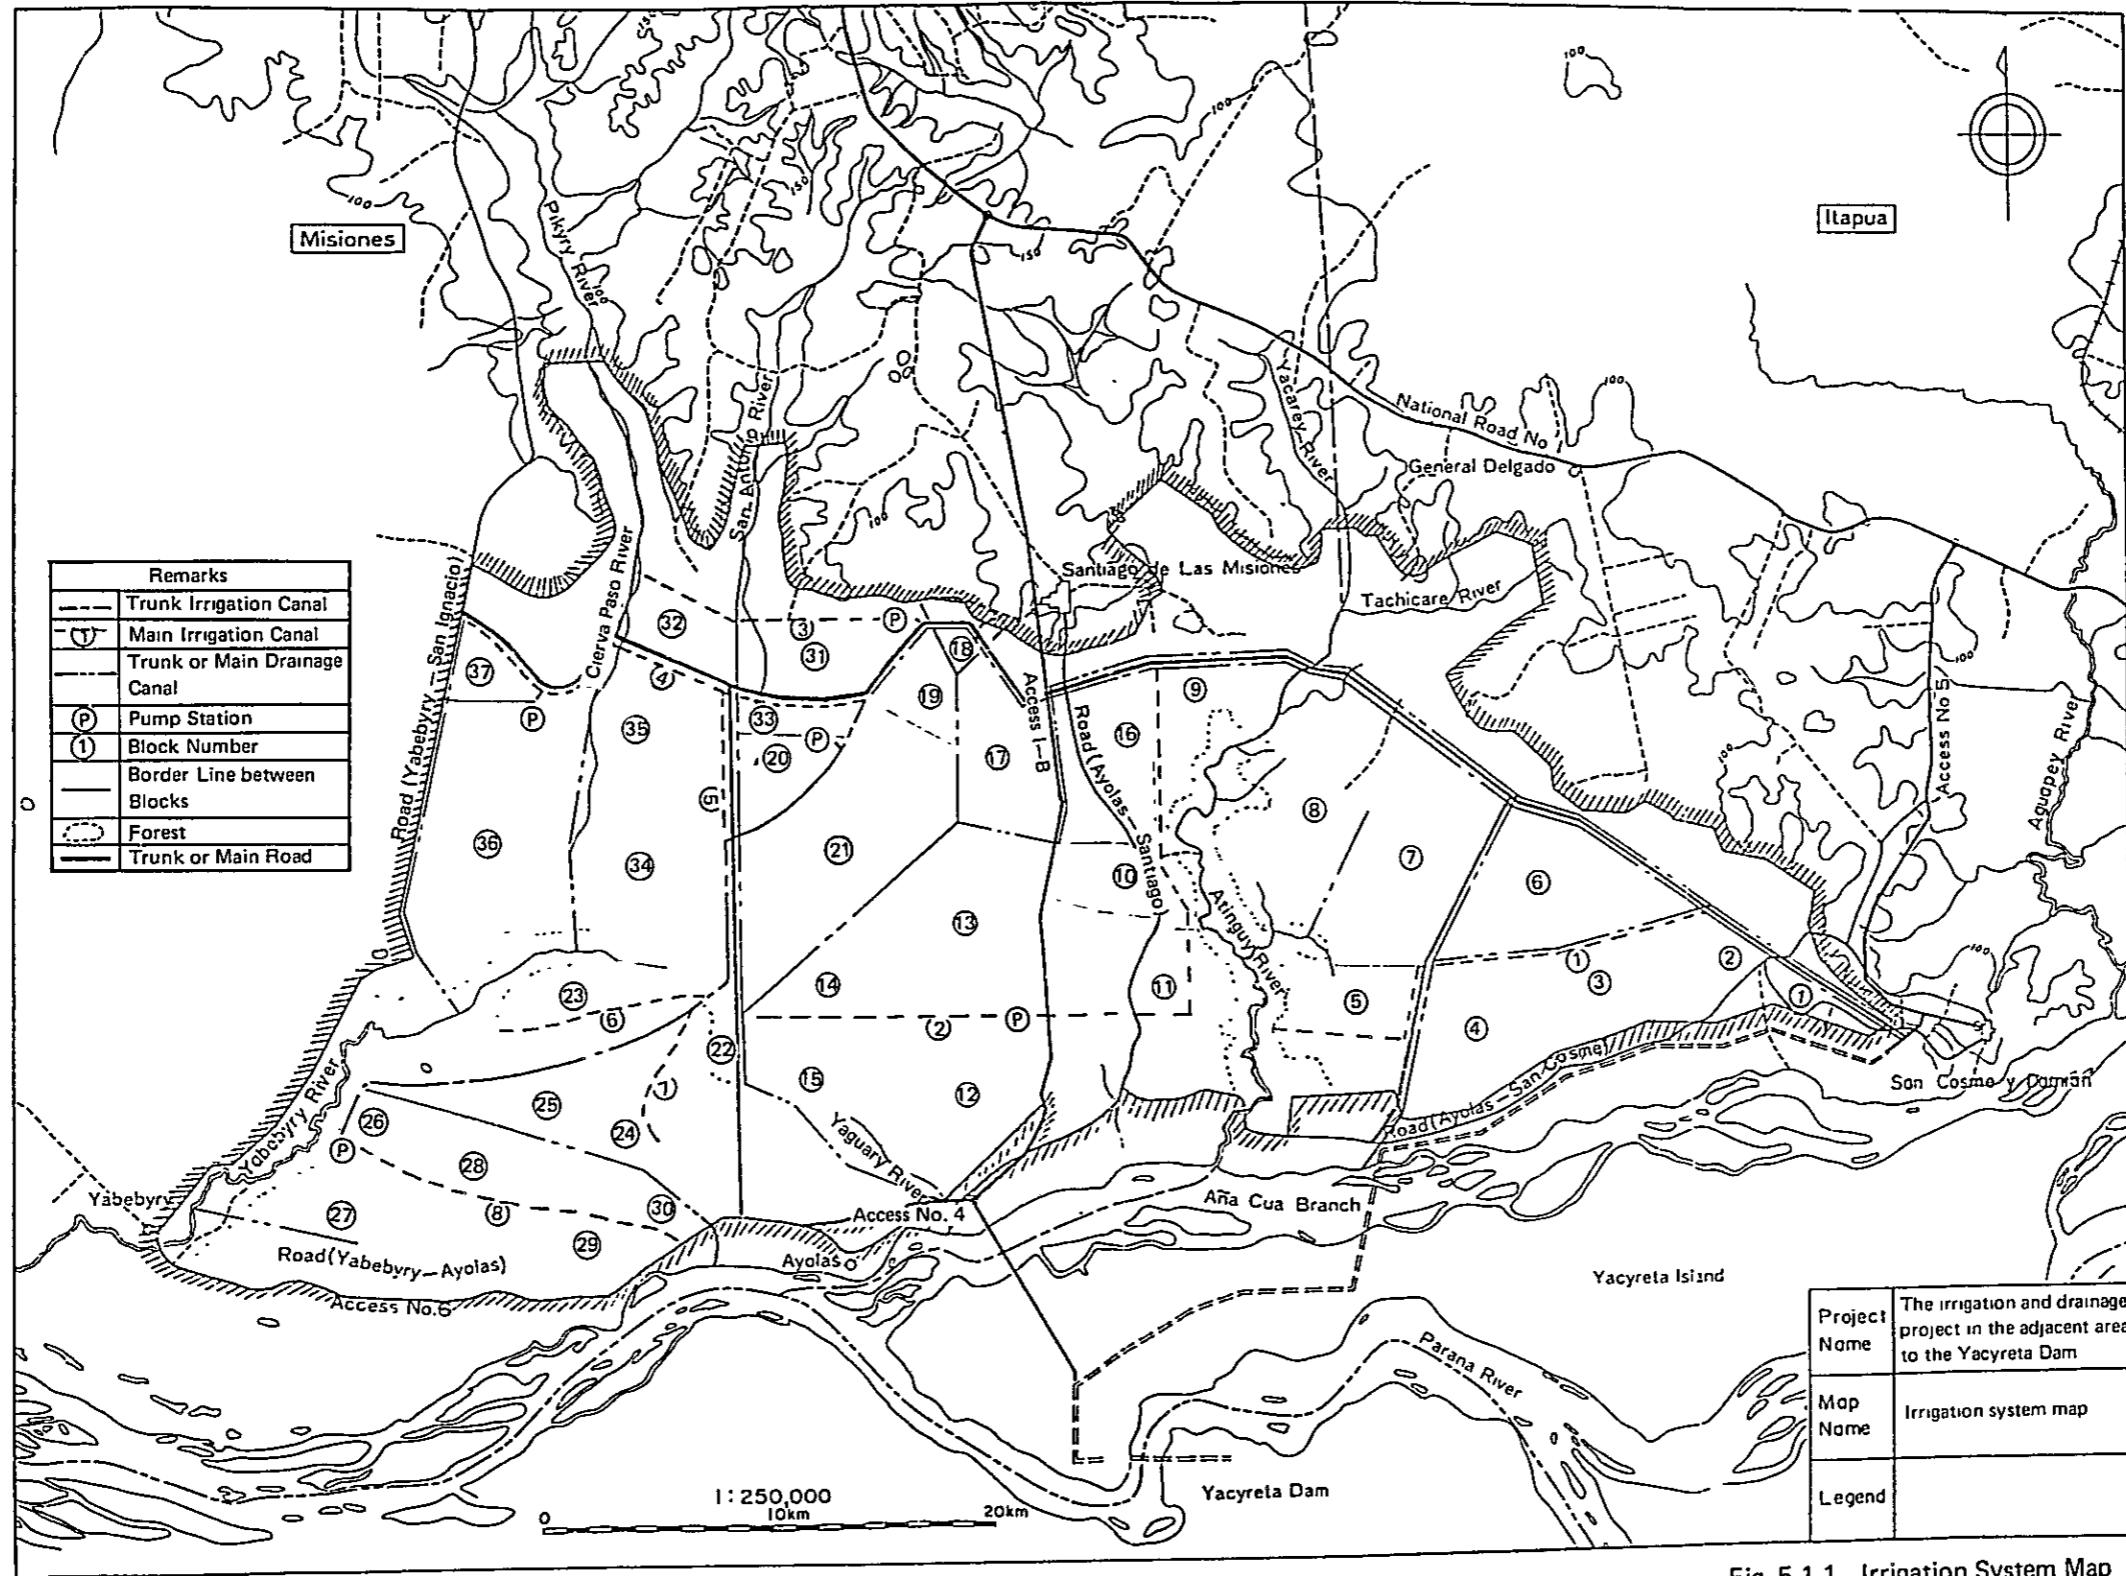

| Block No. | Agricultural land |             |       | Driving channel, etc. | Grand total | Remarks         |

### 5.1.3 Irrigation plan

#### (1) Crop water requirement

In the calculation method of potential evapotranspiration, there are the 4 typical examples of the Modified Penman Method, Blaney-Criddle Method, Solar Radiation Quantity Method and Pan Evaporation Method. In this plan, however, it shall be performed by the Modified Penman Method which is said to be the most accurate by FAO.

#### 1) Meteorological data

The meteorological data used in the calculation of the potential evapotranspiration must be the data which represents the meteorology of the project area.

There are 9 meteorological observatories in the periphery of this project area but as the observation period ranges over a long period and the observation places neighbor the project area, the data of the Yacyreta observatory under the jurisdiction of the Ministry of National Defense shall be used this time. (See Table 5-1-3)

Data necessary for calculation under the Modified Penman Method are temperature, humidity, wind speed and duration of sunshine as shown in Table 5-1-4. However, since observation on duration of sunshine is not performed at the Yacyreta observatory, that of the Encarnacion observatory shall be used.

Table 5-1-3 Dimensions of Meteorological Data for Calculate

| Item                         | Observatory             | Data used                       |
|------------------------------|-------------------------|---------------------------------|
| Daily mean temperature       | Yacyrete obserbatory    | Average of 10 years 1971 - 1980 |
| Daily mean relative humidity | "                       | "                               |
| Daily mean wind velocity     | "                       | Average of 6 years 1975 - 1980  |
| Daily mean sunshine duration | Encarnacion observatory | "                               |

Table 5-1-4 Meteorological Data for Calculation

| Item                            | Jan. | Feb. | Mar. | Apr. | May  | Jun. | Jul. | Aug. | Sep. | Oct. | Nov. | Dec. |
|---------------------------------|------|------|------|------|------|------|------|------|------|------|------|------|
| Daily mean temperature °C       | 26.3 | 25.9 | 24.5 | 20.8 | 18.0 | 15.9 | 16.2 | 16.6 | 18.7 | 21.2 | 22.9 | 25.4 |
| Daily mean relative humidity %  | 74   | 75   | 77   | 76   | 80   | 80   | 77   | 77   | 72   | 73   | 71   | 72   |
| Daily mean wind velocity K not  |      | 6    |      | 5    |      | 6    |      | 7    | 7    | 7    | 7    |      |
| Daily mean sunshine duration hr | 7.9  | 8.6  | 5.9  | 7.1  | 5.5  | 5.6  | 5.5  | 5.8  | 7.0  | 5.8  | 7.3  | 8.6  |

|                                |          |                                |     |
|--------------------------------|----------|--------------------------------|-----|
| Mean maximum relative humidity | Over 90% | Mean wind speed during daytime | 2.0 |
|--------------------------------|----------|--------------------------------|-----|

However, there are meteorological observatories established by the Yacyreta Public Corporation and this study group in and around planned area, therefore data can be analyzed jointly after collected.

Moreover, there are meteorological observatories established by the Yacyreta Public Corporation and survey mission for the purpose of future study in the project area and its environs and it will become possible to perform joint analysis after data storing.

2) Potential evapotranspiration

The standard potential evapotranspiration calculated by the Modified Penman Method (ET<sub>o</sub> mm/d) is as shown in Table 5-1-5. (It is said that this value contains an error of ±10% in the summer season.)

Table 5-1-5 The Standard Potential Evapotranspiration

(mm/d)

| Mon | J   | F   | M   | A   | My  | Ju  | Jy  | A   | S   | O   | N   | D   |
|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| ETo | 7.6 | 7.4 | 5.2 | 4.9 | 3.0 | 2.5 | 3.0 | 3.3 | 5.0 | 6.1 | 7.5 | 8.3 |

3) Crop water requirement (ETcrop)

The crop water requirement (ETcrop) is obtained by multiplying the standard potential evapotranspiration (ETo) by the crop coefficient (Kc) and the crop coefficient (Kc) is set up based on the "Irrigation and Drainage paper Volume No. 24 - Crop Water Requirement" of FAO. The planned species of paddy shall be of the CICA variety and the crop water requirement (ETcrop) shall be calculated by making the planting duration for the period of 40 days from October 20th and the cropping period for the period of 140 to 150 days. Moreover, the crop coefficient shall be deducted by 20% during the non-ponding period. The crop coefficient is shown in Fig. 5-1-3.

Fig. 5-1-3 Crop Coefficient of Paddy Rice

4) Study of crop water requirement

Upon calculation by utilizing Table 5-1-5 and Fig. 5-1-3, the crop water requirement became as shown in Table 5-1-6.

Table 5-1-6 Crop Water Requirement

| Mon.                    | Nov.      | Dec.      | Jan.     | Feb.     | Mar. |
|-------------------------|-----------|-----------|----------|----------|------|
| ET <sub>o</sub> mm/d    | 7.5       | 8.3       | 7.6      | 7.4      | 5.2  |
| K <sub>c</sub>          | 11/7      | 1.1(0.88) | 1/7 1.05 | 2/7 0.95 | 3/6  |
| ET <sub>crop</sub> mm/d | 8.3 (6.6) | 9.1 (7.3) | 8.4 8.0  | 7.8 7.0  | 4.9  |

By the way, the mean value of the crop water requirement during the period from December 16th to December 31st was 7.5 mm/day according to the investigation of daily water requirement in depth and it was a value of about 18% lower than the calculated value of 9.1 mm/day.

There lies the possibility of the meteorological conditions changing in the future when the Yacyreta Dam is completed and the land reclaimed to paddy field progresses in the area. However, the calculated value for the planned crop water requirement shall be adopted and checking and study shall be promoted while providing reference to the results of continued investigations and future researches.

(2) Irrigation method

The rice after direct planting of rice-seeds is cultivated in the field without inundation for about 1 month and after this, the inundation is continued up until harvesting. The irrigation method must be one corresponding to the water management method during the growing stage. Moreover, since it is a large-sized rice crop operation, it is preferred that the water management labor force is small.

Since the soil within the area has a small intake rate and the downward loss in surface irrigation is small, it is suitable for storage irrigation. There is a comparatively uniform rainfall during the cropping period and the rainfall can be effectively used by providing a border and storing the rainfall. Since the space of borders can be

widely set as the topographic features within the area is flat and the slope is also small, the water management labor force can be minimized.

From the above-mentioned fact, the irrigation system shall be of the storage irrigation system utilizing the contour levee.

(3) Water management and water requirement

Water management by direct planting of rice-seeds in field without inundation can be classified into the following 3 stages.

- a. First stage: Stage from directly after the planting of rice-seeds up until just prior to tillering. The soil moisture is controlled with the wilting point as the lower limit. The rainfall is mainly used and the shortage is supplied by irrigation water.
- b. Second stage: Inundation of the paddy field is performed just before tillering. It shall be made of the prescribed inundation depth within the range that it does not become an obstacle to tillering.
- c. Third stage: The prescribed inundation depth is maintained up until inundated.

Fig. 5-1-4 Graphical Figure of Water Management

When the above-mentioned stages are represented, they become as shown in Fig. 5-1-4.

The various elements of the irrigation plan are determined as follows from the physical properties of the soil.

- |  |           |
|--|-----------|
| a. Designed groundwater level at the time of drained paddy field   | GL-700 mm |
| b. Effective root zone at the time of drained paddy field  | 400 mm    |
| c. Volume rate of soil   | 60%       |
| d. Total available moisture percentage (At drained paddy field)  | 20%       |
| e. Total available moisture (TAM)  | 80 mm     |
| f. TRAM (Total readily available moisture) (TRAM/TAM = 0.5)  | 40 mm     |
| g. Invalid moisture percentage   |           |
| Dry side   | 10%       |
| Wet side   | 10%       |
| h. Necessary moisture amount for making it of saturated condition from the field capacity condition.                 |           |
| $h = 400 \times 0.1 + 300 \times 0.1 \times 1/2 =$   | 55 mm     |
| i. Necessary moisture amount for obtaining the prescribed inundation depth (60 mm) from the wilting point condition. |           |
| TRAM+h+inundation amount = 40 + 55 + 60 =  | 155 mm    |

#### 1) Seasonal water requirement

An intermittent irrigation utilizing the peak water requirement is performed in the first stage. The daily irrigation amount is 40 mm (TRAM) and the number of days of intermittent irrigation shall be for the period of 5 days.

In the second stage, inundation (average 60 mm) shall be completed during the period of the 6 days after 25 days from planting of the rice-seeds. Moreover, the soil moisture shall be saturated by immediately before the starting of inundation.

In the third stage, the daily crop water requirement shall be supplied.

Table 5-1-7 Seasonal Water Requirement

| No. | ET <sub>o</sub> | K <sub>c</sub> | ET <sub>crop</sub> | P    | PUD  | TOTAL |
|-----|-----------------|----------------|--------------------|------|------|-------|
|     | mm/d            |                | mm/d               | mm/d | mm/d |       |
| ①   | 6.1             | 0.88           | 5.4                | -    | -    | 5.4   |
| ②   | 7.5             | 0.88           | 6.6                | -    | -    | 6.6   |

ET<sub>o</sub>: Standard potential evapotranspiration

K<sub>c</sub>: Crop coefficient

ET<sub>crop</sub>: Crop water requirement

P: Percolation

PUD: Water for inundation

The seasonal water requirement according to stages shall include the crop water requirement, percolation quantity and duty of water for initial inundation, and shall be calculated as shown in Table 5-1-9 to Table 5-1-7.

(4) Effective rainfall

1) Initial period of first stage

This is the initial stage of direct planting of rice-seeds in field without inundation and the land is of well drained field condition. Therefore, similarly as in the case of surface irrigation for upland, the effective rainfall is defined as follows:

The value deducting the available moisture amount of the soil at just before the rainfall from TRAM (Total Readily Available Moisture) shall be made the upper limit of the effective rainfall. The daily rainfall of less than 5 mm shall be made invalid and on daily rainfall of more than 5 mm, it shall be considered that 80% of the rainfall is used.

2) After the latter period of first stage

In this stage when the rice plant has grown and the danger of overhead inundation has become small, the effective rainfall is defined as follows:

The daily rainfall of less than 5 mm shall be made invalid and in case of daily rainfall of more than 5 mm and less than 80 mm, 80% of the rainfall shall be made valid. When the daily rainfall exceeds 80 mm, 80% of the rainfall ( $80 \text{ mm} \times 0.8 = 64 \text{ mm}$ ) shall be made valid.

It is necessary to build the structure of levee with sufficient margin for utilizing the rainfall effectively. Moreover, it is necessary that water management reliably copes against rainfall.

The effective rainfall during the cultivation period (From October 20th to April 20th of following year) from the year of 1969 to 1979 are as shown in Table 5-1-8.

The calculation of water balance shall be performed by using the daily rainfall for the years of 1977 to 1978 which is the second in ranking and the probability of continuous drought days during the cultivation period corresponds to 1/5. Moreover, the detailed study of effective rainfall is shown in the Appendix.

Table 5-1-8 Rainfall and effective rainfall

| Cropping season | Cropping season  |                  |                  |                  |                  |                  |                  |  |  |  |  |  | Total              | Order |

(5) Calculation of water requirement

The calculation of net water requirement during the cultivation period is performed under the following conditions.

- |                                  |   |
|----------------------------------|---|
| a. Cultivation period            | Period of 140 to 150 days from October 20th   |
| b. Planting of rice-seeds period | Period of 40 days from October 20th   |
| c. Starting of inundation        | To be completed in 6 days from the 25th day after planting of rice-seeds.           |
| d. Calculation year              | From October 20, 1977 to April 20, 1978.  |
| e. Calculation unit              | Every 5 days  |
| f. Cultivation ratio             | To be divided into 40 blocks from the 40th day of the planting of rice-seeds period |

The results of the calculation performed with Table 5-1-9 are as shown below.

- |                                |                            |
|--------------------------------|----------------------------|
| a. Peak net water requirement  | 13.4 mm/day                |
| b. Total net water requirement | 1,095.1 mm/cropping season |
| c. Effective rainfall          | 472.4 mm/cropping season   |

The seasonal water requirement which has been used in the calculation is that which has been calculated based on the results of field investigation and they should be revised in the future by studying the continued observation data. The designed maximum net water requirement in the planning of this year shall be made 13 mm/day (= 1.5 l/sec/ha) from the above-mentioned results.

(6) Irrigation efficiency

Calculation of the design amount of intake water shall be performed by estimating the loss in the net water requirement and this loss percentage shall be set with the irrigation efficiency. The irrigation efficiency shall be determined from many factors such as the size of the field, shape, conditions of irrigation facilities, water management setup, etc. In this program, this efficiency shall be classified into the field efficiency, water-conveyance efficiency and

Table 5-1-9 Calculation of Water Requirement

| Date                                     | 11/1 | 12/1                               | 1/1  | 2/1  | 3/1  | 3/19                         | 180  |      |      |      |      |  |      |      |      |       |      |                          |      |      |      |       |      |                          |      |      |      |       |      |                            |      |      |      |      |      |

management efficiency and each shall be respectively established.

a. Field efficiency

This efficiency has considered the irrigation irregularity, etc., of the field. In case of this area, the topography is comparatively flat and as land grading machineries for farming are also introduced, it can be considered that ponding irregularity does not exist much. On the other hand, inundation continues up until harvesting time and water release is not made intermediately. Moreover, the underground percolation is separately added to the water requirement in depth. From the above-mentioned, the field efficiency shall be based on actual examples of other projects and made 80%.

b. Water-conveyance efficiency

This is the efficiency which concerns water-conveyance by canal from the water source up to the field. The basic irrigation canal, etc., of this plan are unlined canals. The results of leakage survey of existing irrigation canals are few and in places with large leakage, it has been planned to reduce leakages by earth lining. Moreover, the arrangement of facilities, operation methods, etc., are been studied for canal management so that a canal management conforming to the water demand becomes possible. On the other hand, all beneficiaries are organized as water users and are guided and supervised so that a favorable rotation irrigation is performable.

Upon considering these and the evaporation amount from free water surface, the water-conveyance efficiency with reference to enforcement examples of other projects shall be set at 80%.

c. Management efficiency

This is the efficiency concerning diversion management in canals. In case of this program, the establishment of a management facility and management setup intending the further efficiency of water use is planned and it is considered that an effective management can be made. However, since the canals are big and long and the number of diversion facilities are extremely many, the management efficiency based on actual examples of other projects shall be made 90%.

d. Integrated efficiency

This efficiency is that which has combined the field efficiency, water-conveyance efficiency and the management efficiency and it shall be made 57.6% ( $80\% \times 80\% \times 90\%$ ).

(7) Designed unit water requirement

From the overall efficiency of 0.576 obtained in the foregoing item (6) on irrigation efficiency and the maximum net water requirement of 1.5  $\ell$ /sec/ha obtained in the foregoing item (5) on calculation of water requirement, the design amount of intake water (gross water requirement) becomes  $1.5 \ell/\text{sec}/\text{ha}/0.576 = 2.6 \ell/\text{sec}/\text{ha}$ .

(8) Total duty of water, maximum amount of intake water

Since the paddy-rice plant cultivation of this area adopts a 3 year crop rotation system with the use as a grazing land, the actual irrigated area is 39,940 ha, that is, one-half of the irrigated area of 79,880 ha.

From the above obtained value, the total duty of water during a cropping season becomes as follows:

$$39,940 \text{ ha} \times 1,095.1 \text{ mm} \doteq 437,000,000 \text{ m}^3/\text{cropping season}$$

The maximum amount of intake water becomes as follows:

$$39,940 \text{ ha} \times 2.6 \ell/\text{sec}/\text{ha} = 103.8 \text{ m}^3/\text{sec}.$$

## 5.2 Drainage Plan

### 5.2.1 Basic policy for drainage plan

The project area for this plan is a flat low swamp of 90 to 60 m in altitude gently sloped from north to south with ever-inundated plate in the middle, and is surrounded by the hilly lands extending in the north and east rolling between 90 and 150 m in altitude where the National Road No. 1 is passing nearly along the ridgeline, flat large Neembucu swamp to the west, and the Parana River to the south.

Drainage from the area is carried by the Atinguy River and the Yabebyry River of large river, and the Yaguary River of small river and artificial drainage canals, into the Parana River, but due to insufficient effect of these, the project area is often or almost always inundated by the water which flows in from the hinterland as well as the water which runoff in the area.

Based on the cultivation plan and the land use plan, this area will be divided into Area A and Area B, where wheat and soybean in the Area A and paddy in the Area B are planned as the primary products, but when seen from the weather and topographical conditions and from the cultivation system, it is said that the essential condition for securing stable production of these is execution of the drainage work which will cover the whole project area.

To outline the drainage plan for such an ever-inundated area in this year, analysis is performed for the inundated condition and the caused, drainage plans are formulated for several cases based on the results obtained from the analysis, and the optimum drainage plan is selected out of such plans, by means of simulation analysis using the mathematical model made for the set conditions.

### 5.2.2 Rainfall runoff analysis

#### (1) Methods for rainfall runoff analysis

In the project area, inundates are caused by the rainfall which runoff from the hinterland and the rainfall in the area. This runoff of rainfall can be analyzed by either of the following methods:

- 1) Method by measured values
  - a. Method by measured flow rate
  - b. Method by measured water level or by trace of inundates

- 2) Method by formula for flow rate (Rational method)
- 3) Method by analysis for measured precipitation and runoff
  - a. Inundated frequency method
  - b. Specific flow rate method
  - c. Coaxial method
  - d. Unit hydrograph method
  - e. Tank model method
- 4) Method by theoretical formula
  - a. Runoff function method
  - b. Storage function method
  - c. Characteristic method
  - d. Combined characteristics method

These methods have their own features, and as the data are not enough for this area and the topography is quite flat there, the Characteristic method which suit this condition is used for analysis.

(2) Rainfall runoff analysis by Characteristic method

1) Method of analysis Characteristic method

Rainfall in the project area and of hinterland are assumed to flow into rivers or drainage canals in the condition as given in the figure below:

Fig. 5-2-1 Rainfall Runoff Model by Characteristic Curve Method

Based on the assumption that flow on this slope can be approximately equalized by Maning Formula, the inflow condition is analyzed by Characteristic method using a computer. (The formula used and other details are described in the Appendix)

## 2) Runoff model

Various basic values for the project area and hinterland are required for the runoff analysis. For example, the coefficient of equivalent roughness depends on whether these are to be used as forests, fields or paddy fields, and the slope pitch and slope length will differ by topography. Accordingly, the set conditions are modelled so as the average runoff phenomena of the project area and the hinterland are analyzed, and the analysis is performed using the mathematical model.

### a. Estimated design rainfall

#### (a) Rainfall observatory

The estimated design rainfall is the basis for drainage plan, and the analysis is performed carefully. For details, refer to Chapter 2 General Plan and Survey, 2.1 Meteorology and Hydrology. Around the project area, rainfall observatories are located at 3 places by Department of Meteorology, Ministry of National Defence, 5 places by the Yacyreta Public Corporation, and 3 places by this survey team, totalling 11 observatories. After analyzing suitability of these by Thiessen Method and other methods, data by Yacyreta Observatory, Ministry of National Defence, will be used in formulating the master plan.

#### (b) Continuous rainy days

To formulate the drainage plan, it is necessary to study which to take, diurnal rainfall, continuous 2-day rainfall or continuous 3-day rainfall, for the design rainfall according to the objective, scale and economy of work. After analyzing the occurrence of continuous rainfall for the past 18 years using the data by Yacyreta Observatory, it is understood that the diurnal rainfall is about 78%, 2-day rainfall is about 16%, indicating the high probability of diurnal rainfall,

and that rainfall of 150 mm, more or less, to be used in the plan is often seen actually as diurnal rainfall. Therefore, this plan will be formulated for diurnal rainfall.

(c) Probability rainfall

As the result of the calculation of Iwai method using the rainfall data of Yacyreta Observatory, the 1/10 year probability diurnal rainfall of 164.4 mm/day is obtained. This rainfall is used to be the design value for simulation.

For details of probability rainfall analysis and the data, refer to 2-1 Meteorology and Hydrology, and to the Appendix.

(d) Rainfall pattern

Using 3 units of auto-pluviometers installed for this survey, the time history analysis of rainfall will be performed, but for this year's planning it is assumed that the rain would fall uniformly during 12 hours.

(e) Rainfall losses

The rainfall losses is obtained by subtracting the direct runoff from the total precipitation, and it is generally considered to be 50 mm, more or less, for the case of paddy fields. The auto-level gauges and auto-pluviometers were installed in the 2nd year of the survey in this area and is collecting the data at the moment, but for this year's plan the rainfall losses is supposed to be same for both the project area and the hinterland, and the runoff analysis is performed for the cases of 0.0 mm, 50 mm and 80 mm. The relation of rainfall losses and precipitation is described in the Appendix.

b. Base flow

The base flow will be analyzed after the data by auto-level gauges have been complete. Generally, the base flow is small as compared with the peak flow in case of inundate, and the significance of base flow in view of water use is rather negligible. As the rainfall losses is supposed for above 3 cases this time, the base flow is supposed to be 0.0 m<sup>3</sup> on this stage. Also, the subsurface flow is omitted for the same reason.

c. Equivalent roughness

The equivalent roughness is the most important factor in the runoff analysis and is to be determined from the data obtained by the flow observation, but under the situation that the data are being collected at the moment, it is set to be  $N = 0.5$  for slopes and  $N = 0.05$  for rivers and drainage canals based on the another examples.

d. Models for terminal drainage canals and field in the area

The unit runoff from fields to terminal drainage canals in the area is modelled mathematically as given in Fig. 3-3 of the Appendix. Namely, in the unit runoff, the terminal drainage canal is set to be 2,000 m in length and 1/5,000 in inclination, and the field 500 m in slope length and 1/1,000 in inclination.

e. Runoff model for hinterland

The hinterland is divided into 30 blocks based on the category of topographical condition and drainage system, as given in Fig. 5-2-2, and the elements of each of the blocks such as catchment area, mean slope length, mean inclination of slope, extension of river and inclination of river are set based of the 1/50,000 topographic map, as tabulated in Table 5-2-1.

These blocks when modelled are generally classified into 12 drainage systems as given in Fig. 5-2-3.

(3) Results of rainfall runoff analysis

The runoff in the set mathematical models when analyzed by Characteristic method using computers is as tabulated in Table 3-3 of the Appendix.

Also, the results are tabulated in Table 5-2-2 for the peak runoff, peak runoff time and specific peak discharge, from which the peak time is 8 to 16 hours after start of precipitation when seen in the case of rainfall losses of 0.0 mm, 11 to 21 hours in case of rainfall losses of 50 mm, and 12 to 26 hours in case of rainfall losses of 80 mm; the specific peak discharge is 2.14 to 3.81  $\text{m}^3/\text{sec}/\text{km}^2$  in case of rainfall losses of 0.0 mm, 1.19 to 3.61  $\text{m}^3/\text{sec}/\text{km}^2$  in case of rainfall losses of 50 mm, and 0.72 to 2.79  $\text{m}^3/\text{sec}/\text{km}^2$  in case of rainfall losses of 80 mm.

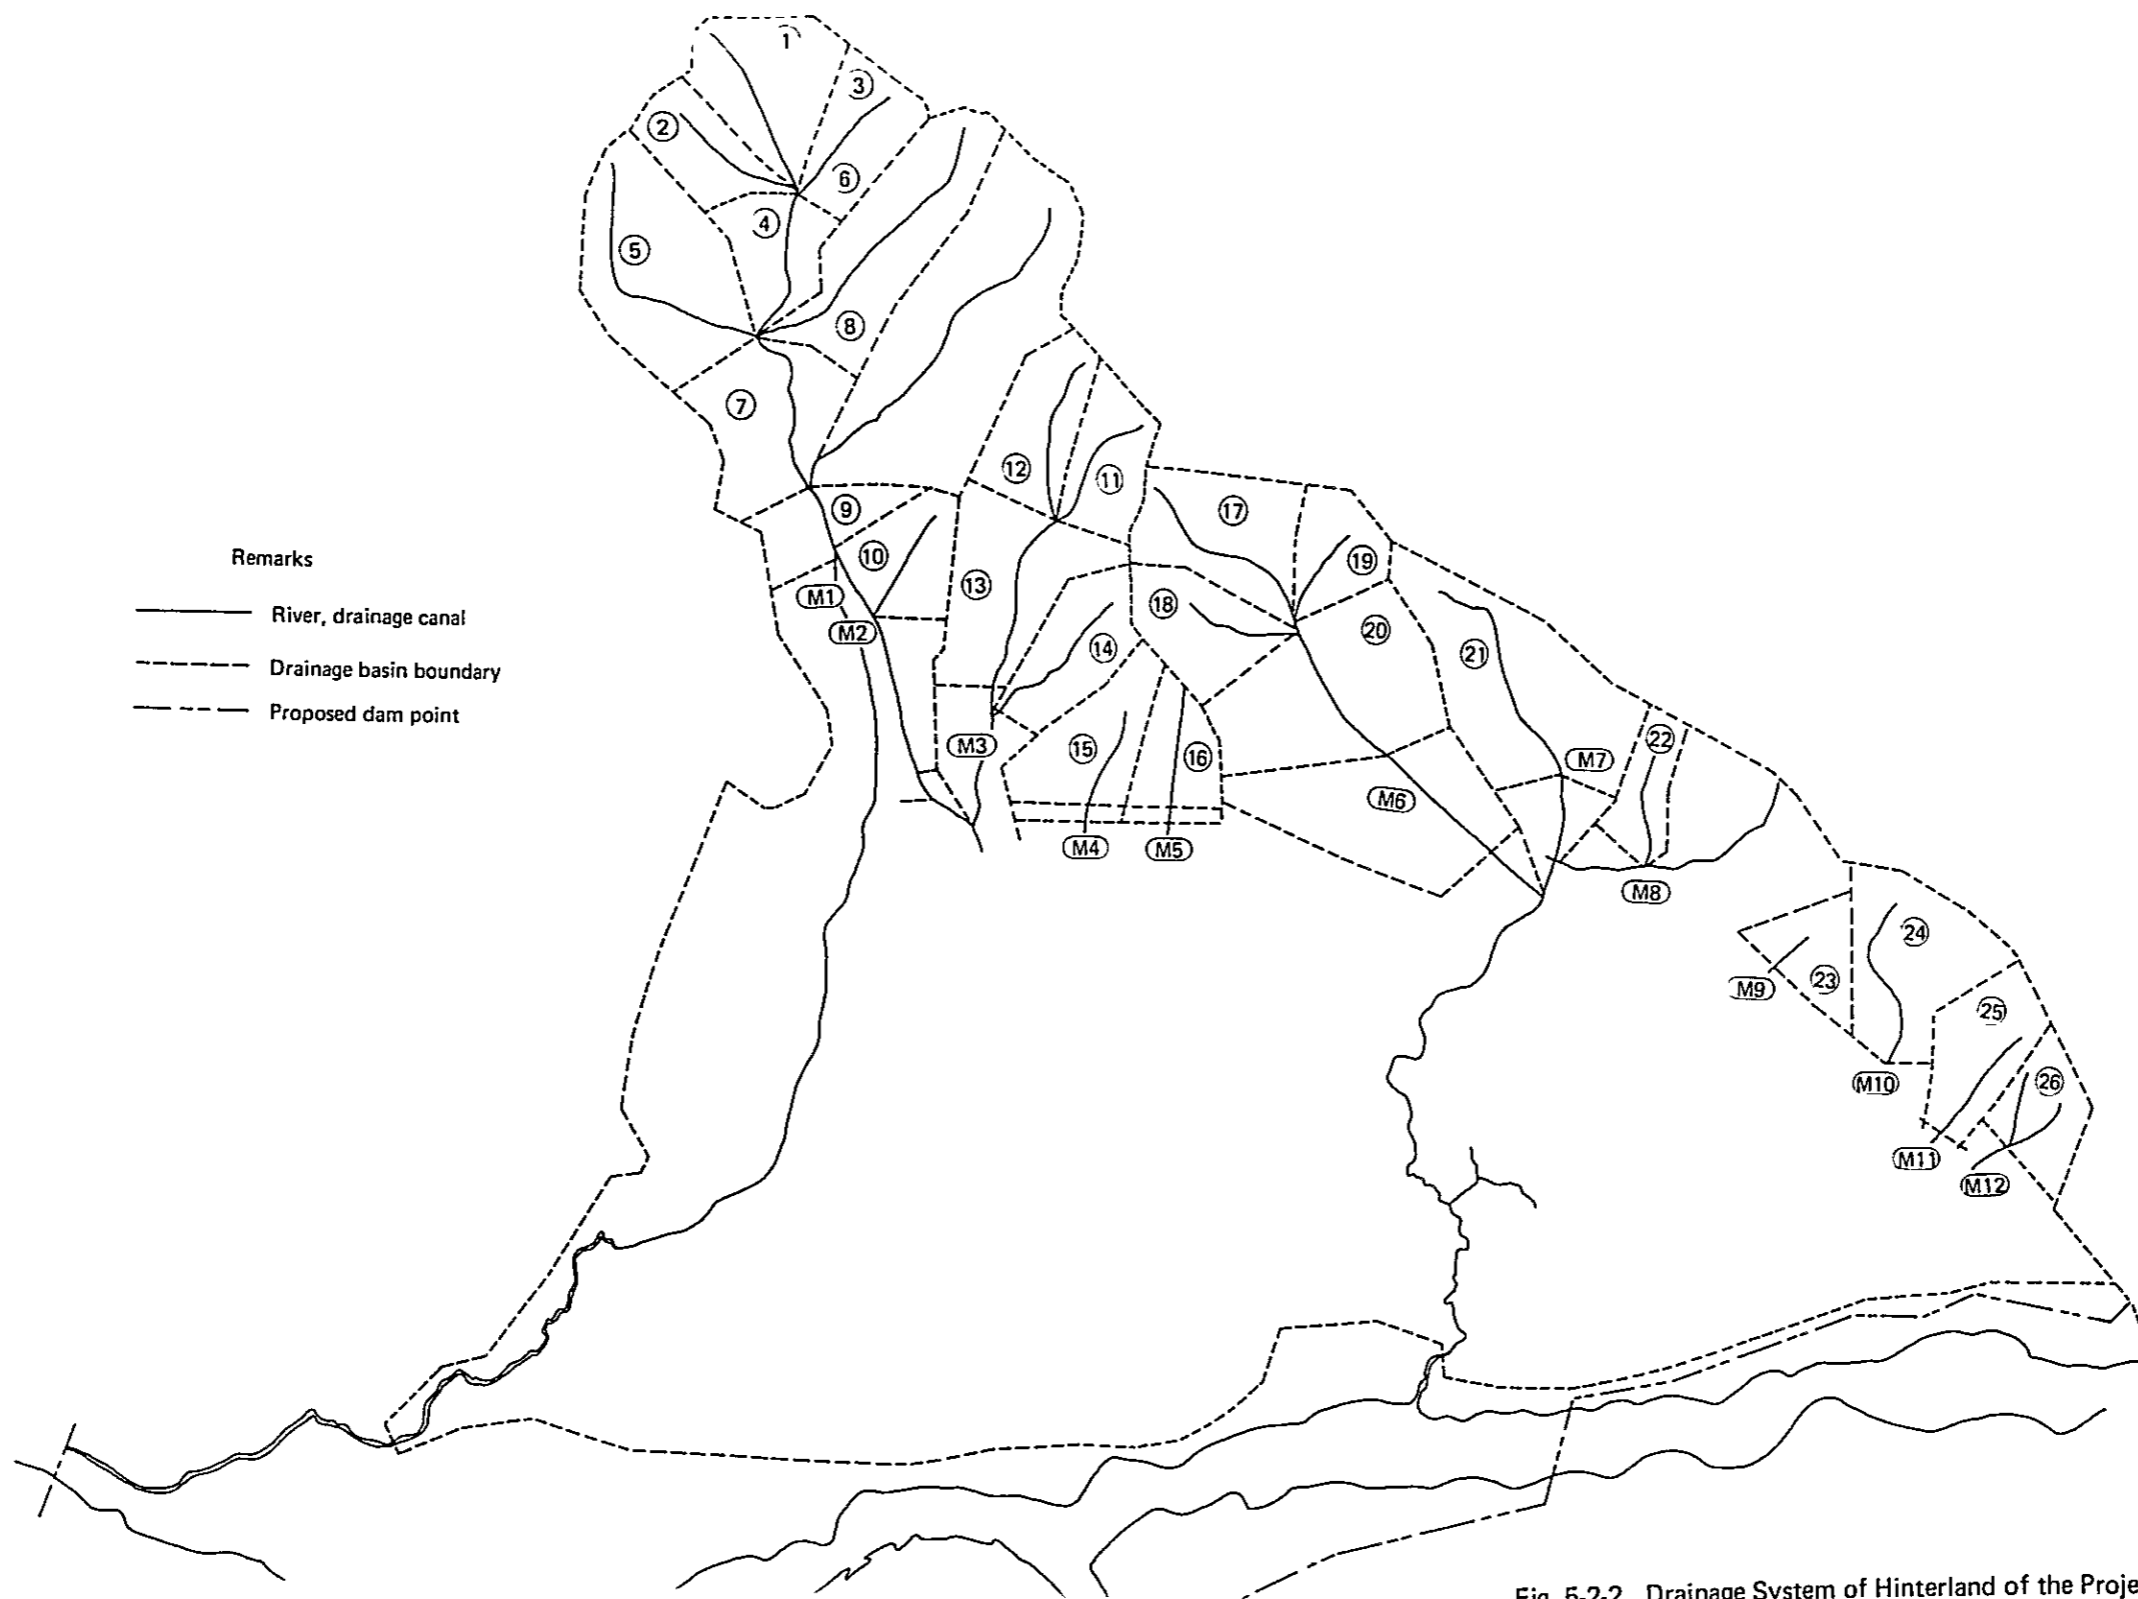

Fig. 5-2-2 Drainage System of Hinterland of the Project Area

Table 5-2-1 Discussion of the Hinterland Block

| Block No. | Number | Catchment area       | Mean slope length | Mean sloping grade | River length | River slope | Remarks                                      |

Fig. 5-2-4

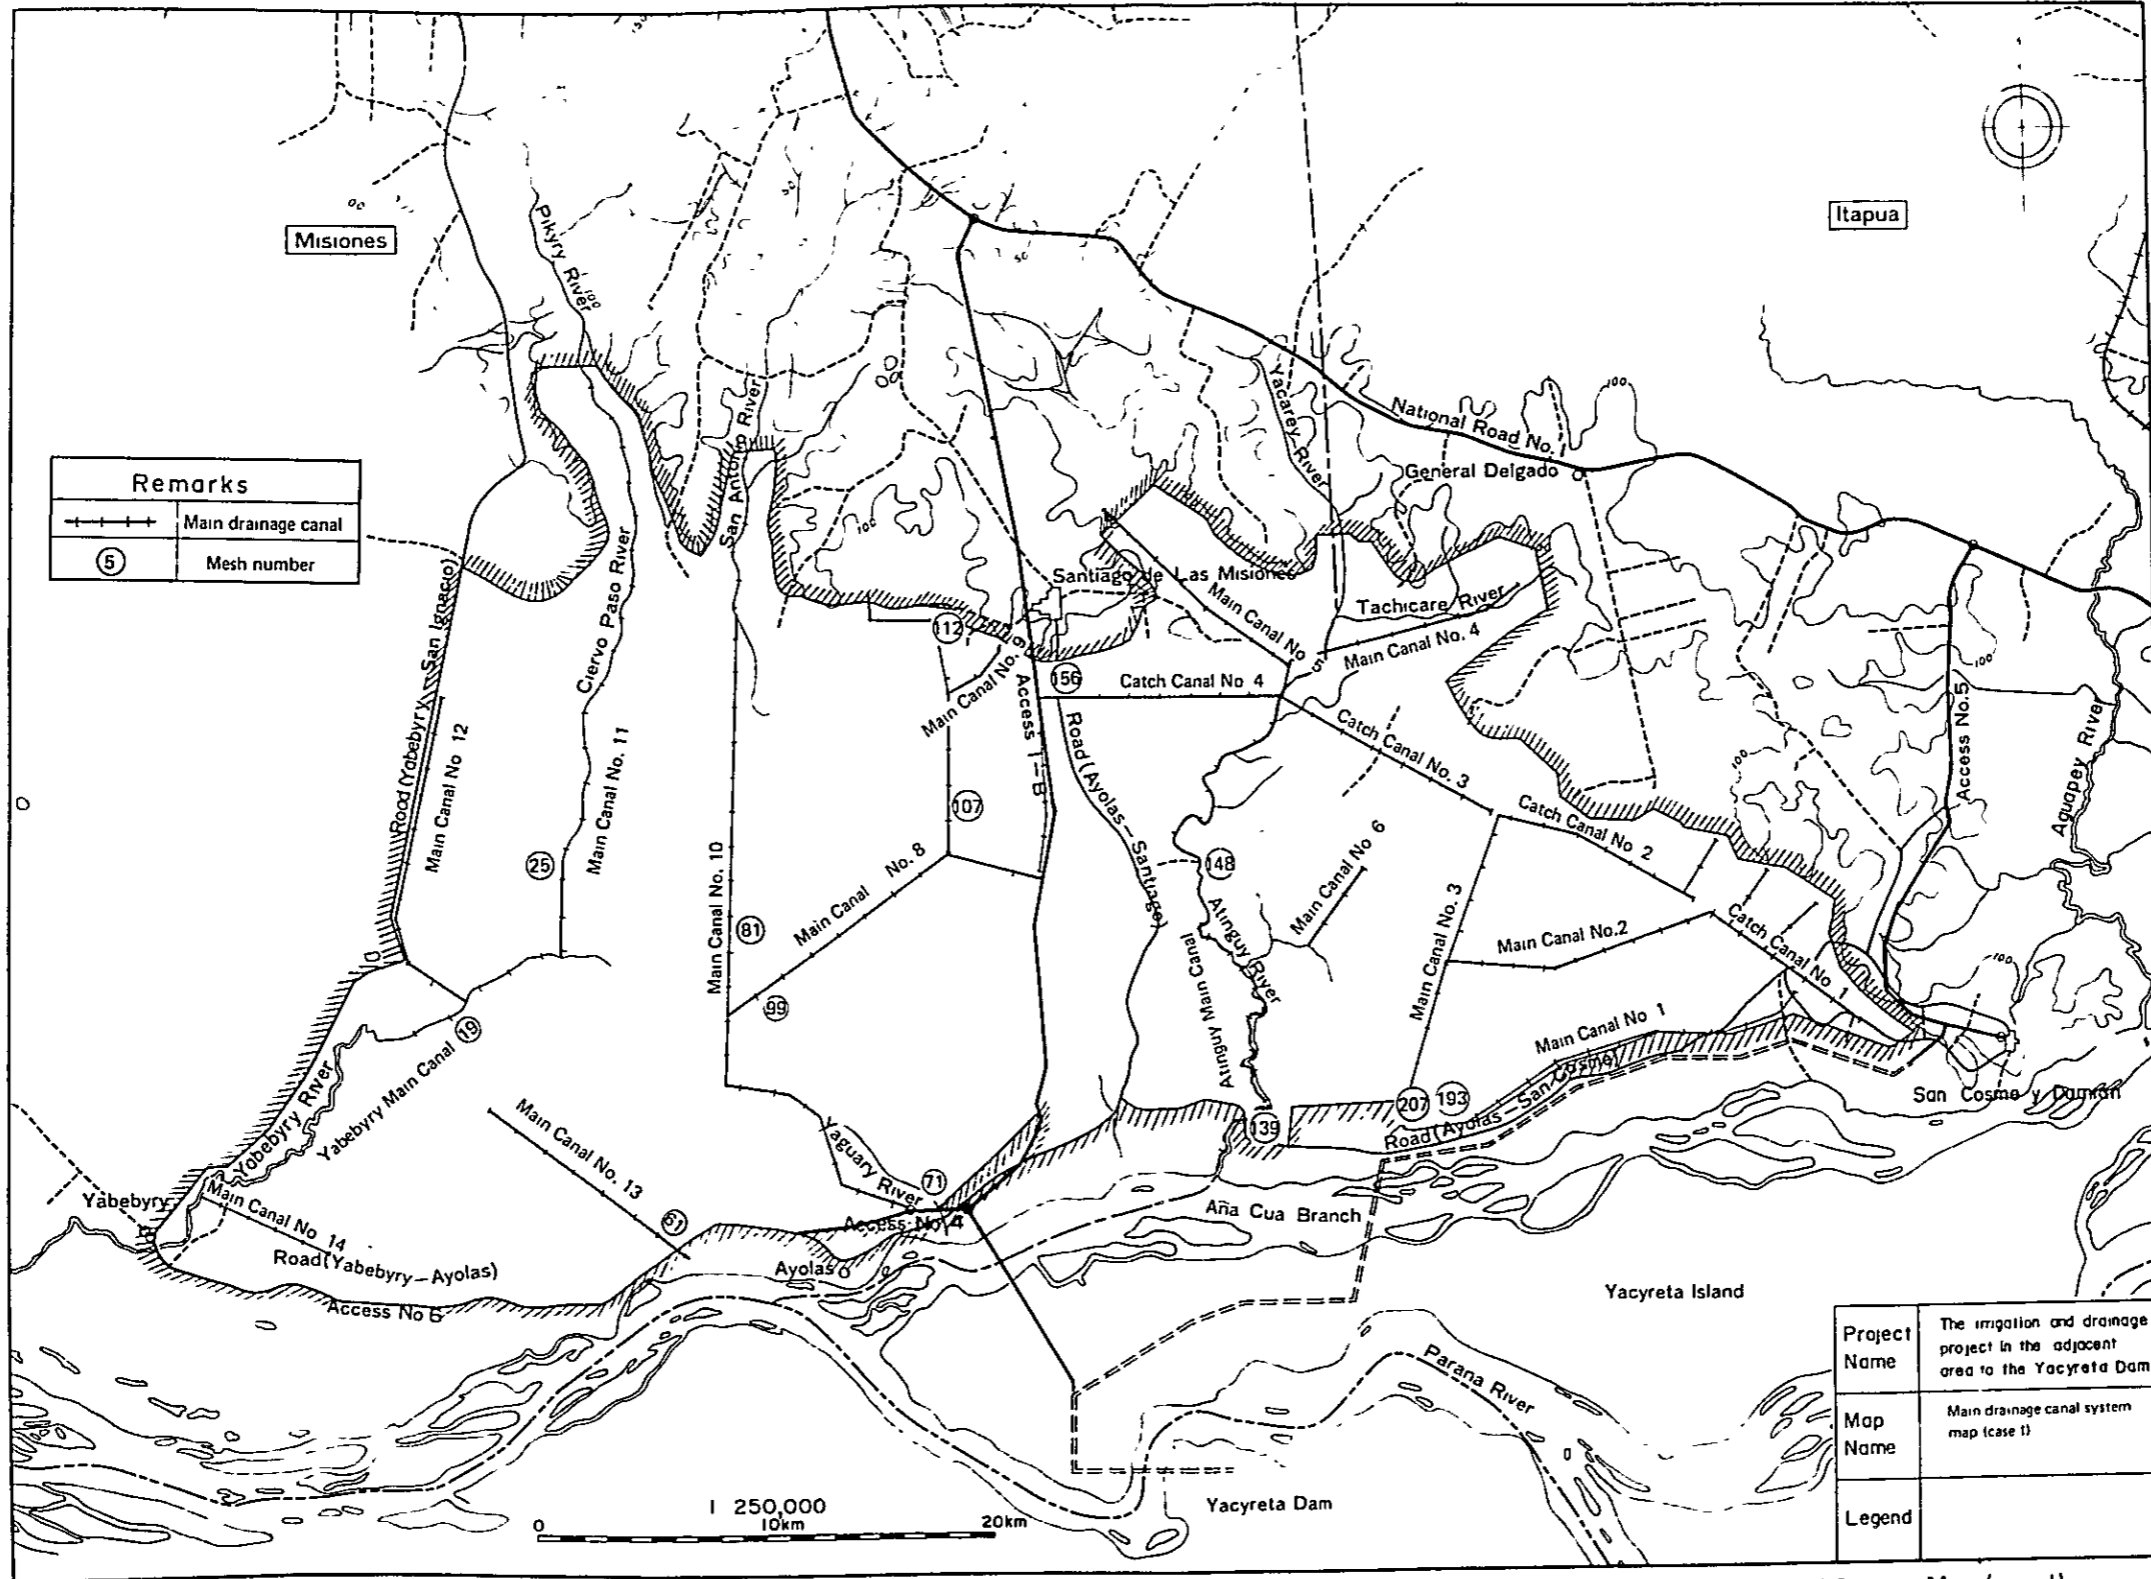

Fig. 5-2-4 Main Drainage Canal System Map (case I)

### 5.2.3 Flow analysis

#### (1) Method of flow analysis

As the planned drainage system of this area, system I given in Fig. 5-2-4 and system II in the Appendix Fig. 4-8 are studied. In both of the systems, innumerable number of lateral canals are connected to the Yabebyry River and other rivers and the main drainage canals to be constructed. As these main drainages are connected to the Parana River, flow in the mouths of canals is an unsteady flow which varies depending on the time due to influence from the water level of the Parana River. As it is considered suitable, for the flow analysis on the drainage canals in such area, to simulate the mathematical model in which the hydraulic facilities are used as the software for computation, it is applied to this plan, too.

#### (2) Flow analysis by mathematical simulation

##### 1) Method of analysis

The method developed by National Research Institute of Agricultural Engineering, Ministry of Agriculture, Forestry and Fisheries, is applied to the flow analysis. The hydraulic calculation of rivers and drainage canals is performed by solving the equation of motion and continuous equation simultaneously for the unsteady flow of open canals. For details of these equation of motion, basic formula for continuous equation, and sequence of calculation, refer to the descriptions in the Appendix.

##### 2) Contents of calculation

To obtain the basic data for preparation of drainage plan by means of this mathematical model simulation, calculations are performed for the drainage systems and other various cases which include the cross section of drainage and so on to be studied in (3) Modelling of the project area in the next section, so as to formulate the optimum drainage plan and to clarify the effects of drainage plan.

#### (3) Modelling of the project area

##### 1) Setting of conditions for calculation

Preparing the mathematical models of the project area based on each of the cases, the conditions for calculations used in the flow analysis

are set as follows:

2) Data for altitudes of main drainage canals and other data

Data such as the bottom heights, inclination of slopes, height of banquettes, of main drainage canals, and altitudes of paddy fields, are determined based on the 1/50,000 topographical map together with the results of surveying performed for the primary portions of the Atinguy River and the Yabebyry River during the 2nd year of the study.

3) Cross section of main drainage canal

The cross section of canal is set for the estimated unit discharges in the following 5 cases:

Case 1: Cross section for  $0.25 \text{ m}^3/\text{sec}/\text{km}^2$  of unit discharge  
(Actual cross sections of the Atinguy River and the Yabebyry River are equivalent to this case.)

Case 2: Cross section for  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$  of unit discharge  
(Cross section which can drain the 1/10 probability diurnal precipitation for 2 days is roughly equivalent to this case.)

Case 3: Cross section for  $1.0 \text{ m}^3/\text{sec}/\text{km}^2$  of unit discharge

Case 4: Cross section for  $2.0 \text{ m}^3/\text{sec}/\text{km}^2$  of unit discharge

Case 5: Cross section for  $3.0 \text{ m}^3/\text{sec}/\text{km}^2$  of unit discharge

The shape of canal's cross section is approximated to the composite trapezoidal cross section to be the standard, as given in Fig. 4-6, based on the results measured and the 1/50,000 topographical map.

For above Cases 2, 3, 4 and 5, the cross sections of which are modeled as the trapezoidal cross sections for simplifying the calculations.

The data for the set cross sections can be referred to in the Table 4-2 of the Appendix.

4) Coefficient of roughness

It is preferable that the coefficient of roughness be determined based on the flow observation and other related measurements to be performed at the site, but under the situation that the data are still being gathered there, the coefficients of the present cross sections of the

Atinguy River and Yabebyry River are set to be 0.05, and the coefficients of other repaired rivers and drainage canals are set to be 0.04.

5) Interval of canal length mesh and time interval for calculation

When calculation is performed with small intervals of canal length mesh and time intervals in simulating the mathematical model, the results can be obtained in detail, but actually, the accuracy is not so improved as expected as compared with time and labor required for analysis using computers. Therefore, meshes and time intervals should be set properly as appropriate. As this plan is still on the stage of master plan to cover such extensive area of nearly 150,000 ha, it would be advisable for obtaining the data in better condition for the planning works when the analysis is first made providing at most 300 of meshes and is further analyzed as necessary in other substitutional plans. Based on this understanding, the mesh is set to be 1,500 m with time intervals of 60 sec.

Additionally, for reducing the meshes in number, the terminal lateral drainage canals are omitted from the model but the flow rates are input as the lateral inflows.

6) Lateral inflow

a. Inflow from the hinterland

Inflow from the hinterland is given as the discharge calculated by Characteristic method.

b. Inflow from fields

For the inflow from the fields, the discharges obtained by multiplying the unit discharge by Characteristic method by control of each mesh is input.

7) Water level of the Parana River (Outer water level)

The water level of the Parana River, outer level, is set to be the level equivalent to 1/10 year probability level (discharge: 30,000 m<sup>3</sup>/sec) out of the estimated water level of Ita Ibate Dam.

#### 8) Planned drainage system

Based on the topographical condition and current drainage system in the project area, the following 2 cases are proposed as the planned drainage systems. By performing simulation on these 2 systems, the one which is more effective will be selected.

##### (System I)

As given in Fig. 5-2-4, it is intended to discharge the water from the area and from the hinterland mostly from the north to the south, by adding 2 of main drainage canals besides existing the Atinguy River and the Yabebyry River.

The model view of the drainage system is given in Fig. 5-2-5.

##### (System II)

As given in Fig. 4-8 of the Appendix, it is intended to discharge most of the rainfall from the hinterland and the project area into existing the Atinguy River and the Yabebyry River, in which relatively large amount of rainfall is to flow from the east to the west.

The model view of the drainage system is given in Fig. 4-10 and 4-11 of the Appendix.

#### 9) Cases calculated

Based on the study made so far, and by simulation analyses for combinations of various cases, the plan which is optimum for this area will be formulated. Such cases are combined as indicated in Fig. 5-2-3, among which 24 cases connected with full lines are analyzed.

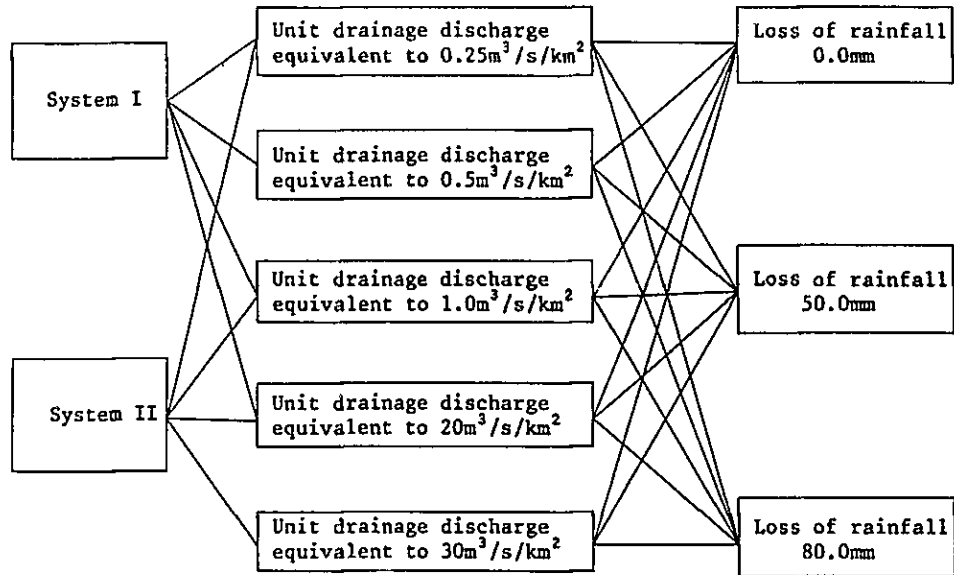

Fig. 5-2-5 Illustrated Drainage System (Case 1)

Table 5-2-3 Calculation Cases of the Simulation

| Drainage canal system | Canal cross section | Loss of rainfall |
|-----------------------|---------------------|------------------|
|-----------------------|---------------------|------------------|

#### 5.2.4 Analysis results

Here, the results calculated of the water level, velocity, discharge and lateral inflow of drainage canals, and the depth of inundation and inundated area in the project area are studied, and the drainage system and cross section of drainage canals which are optimum for the project area are studied.

##### (1) Water level of drainage canal

For the representative points on the drainage canals obtained by simulation, the variation of water level by time is given in Figs. 5-1 and up to 5-24 of the Appendix, and the peak water levels and the timings of occurrence (hours after start of rainfall) are given in Table 5-1 and 5-2 of the Appendix.

For system I of drainage water system in which the rainfall losses is supposed to be 50 mm, the cases in which the cross sections of drainage canal is 0.25, 0.5, 1 and 2 m<sup>3</sup>/sec/km<sup>2</sup>, viz., cases 1-2, 2-2, 3-2 and 4-2 are studied mainly. For system II of drainage canal system, details are described in the Appendix.

##### 1) Yabebyry main drainage system

In Figs. 5-2-6 and up to 5-2-8 are given the variations in water level by time for the Mesh No. 7 which is near the boundary with the downstream area and is the primary point in the Yabebyry Main Drainage System, the Mesh No. 19 right after the point the Main Drainage Canal No. 12 flows in, and the Mesh No. 25 located in the midstream. In case 2-2, no inundation occurs at the point of Mesh No. 19, and inundation does not exceed 30 cm in depth at the point of Mesh No. 7, and inundation exceeding 30 cm in depth continues about 40 hrs.

At either of above 3 points, the water level rises and drops as the cross sections of drainage canals are larger. At the point of Mesh No. 25, where runoff is caused in the upstream by inundated water in case of 0.25 m<sup>3</sup>/sec/km<sup>2</sup> of cross section, a shallow but long continuing inundation is seen.

##### 2) Main Drainage Canal No. 10 System

Figs. 5-2-9 and up to 5-2-14 indicate the variations in water level by time for the Mesh No. 71 located at the downstream of Main

Drainage Canal No. 10, the Mesh Nos. 81 and 99 in its midstream, and the Mesh Nos. 107, 112 and 156 in its upstream.

Inundation does not occur in the downstream and midstream, but occurs in the area between the midstream and upstream.

### 3) Atinguy Main Drainage Canal System

The variations in water level by time for the Mesh No. 139 located in the estuary of the Parana River of Atinguy Main Drainage Canal and the Mesh No. 148 in its midstream, are given in Figs. 5-2-15 and 5-2-16. The reason why the peak occurs in the later part at the point of Mesh No. 139 is that the discharge from the upstream delays in reaching the point where it meets the discharge from the canals relatively close to the point. It is added that, due to the high water level in the Parana River, inundation occurs also in the case in which the cross section of drainage canal is  $2 \text{ m}^3 / \text{sec}/\text{km}^2$ .

### 4) Main Drainage Canal No. 3 System

For the Mesh Nos. 193 and 207 which located in the downstream of Main Drainage Canal No. 3 system, the variations in water level by time are given in Figs. 5-2-17 and 5-2-18.

Fig. 5-2-18 Transition Curve of Water Level

## (2) Flow rate of drainage canal

For the representative points on the drainage canals obtained by mathematical simulation, the variations in water level by time are given in Figs. 5-67 and up to 5-114 of the Appendix, and the peak water level and the timings of occurrence are given in Tables 5-5 and 5-6 of the Appendix. In either of the cases, the peak occurs earlier as the point goes upstream, and it takes longer until the water inundated from the upstream and midstream reduces as the point goes downstream.

When the rainfall losses is 50 mm and cross section of drainage canal is  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$  in system I of drainage canal system, viz., case I-2-2, the specific peak flow is 0.526 to  $1.575 \text{ m}^3/\text{sec}/\text{km}^2$ , and the peak flow is  $460.9 \text{ m}^3/\text{sec}$  in the estuary of the Atinguy River and  $468.3 \text{ m}^3/\text{sec}$  in the estuary of the Yabebyry River.

## (3) Condition of inundation

Obtaining the distribution of inundation from the results by the simulation, the maximum depths for each of the cases are figured in Figs. 5-119 ~ 130 and up to 5-152 ~ 163 of the Appendix. To see the variation by time in the distribution of inundation, the condition of inundation in case of rainfall losses of 50 mm observed every 10 hrs. is given in Figs. 5-131 ~ 5-151 and 5-164 ~ 5-177 of the Appendix. In order to facilitate understanding of inundated condition, the maximum depths of inundation are indicated for each of the meshes.

In the case of case I-2-2, the distribution of maximum inundation depths is as given in Fig. 5-2-19, from which it is seen that inundation is caused in most of the area. When this is seen in Figs. 5-138 and up to 5-144 of the Appendix in which variations by time are indicated, it is understood that in 10 hrs of rainfall, inundation has started in relatively large area, particularly from the upstream areas, in 20 hrs, inundation proceeds further toward the downstream areas, in 30 hrs, inundation has started reducing in the upstream areas, and in 40 hrs, inundation have disappeared except for the low areas in the midstream. The inundation area and the rate of inundation area are given in Tables 5-8 and up to 5-13. It is understood that the inundation area reduces as the rainfall losses increases or as the cross sections of drainage canals are enlarged.

(4) Study of drainage canal system

Based on the simulations performed for system I and system II to be the drainage canal systems, the systems in the cases are compared in the following:

Fig. 5-2-20 indicates the inundation depths and inundation rates for the case in which the rainfall losses is 50 mm, and the cross section of drainage canal is varied from  $0.25 \text{ m}^3/\text{sec}/\text{km}^2$  up to  $2 \text{ m}^3/\text{sec}/\text{km}^2$ , from which it is understood that the inundation rate is lower in system I than in system II in either of the size of cross section, indicating higher effect of the former.

(5) Study of cross section of drainage canal

To study the optimum size of cross section for drainage canal, the relation of the cross section of drainage canal (size) and the inundation rate is given in Figs. 5-2-21 and 5-2-22 for system I, and in Figs. 5-179 for system II. The relation when the inundation depth is 30 cm is given in Fig. 5-2-22, from which it is seen that, when the rainfall losses is 50 mm, the effect of drainage starts reducing the rate of increase with the cross section of drainage canal of  $1 \text{ m}^3/\text{sec}/\text{km}^2$  and over, and that the effect turns downward near the cross section slightly larger than  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$ . For the rainfall losses, the one suitable for the features of the area will be set in the 3rd year's study based on the water levels and discharge of rivers for which observation has been underway, and it is expected to be set to 50 mm more or less. If so, the rate of inundation area of more than 30 cm in depth is about 9% in case of cross section of  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$ , and when considering that it satisfies the general requirement for preparation of drainage plan of 10%, it is said that the cross section  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$  is appropriate.

Fig. 5-2-22 Relation between Drainage Canal Section and Inundation Rate (Over 30 cm)

(6) Conclusion

Based on the analysis results obtained so far, system I of the drainage canal system by which effective drainage is expected and the construction work can be proceeded step by step by dividing the project area into sections, is employed.

By system I of drainage canal system, the total length and occupied areas of the main drainage canals are as follows:

Table 5-2-4 Total Length and Occupied Area of Main Drainage Canal

| Name of main drainage canal | Total length   | Occupied area                |
|-----------------------------|----------------|------------------------------|
| Atinguy Main Drainage Canal | 33.0km         | 647.0km <sup>2</sup>         |
| Yabebry Main Drainage Canal | 34.5km         | 830.1km <sup>2</sup>         |

For the cross section of drainage canal,  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$  with which the drainage efficiency is high and the inundation area of more than 30 cm in depth is about 9%, is applied to the plan.

The distribution of inundation areas of more than 30 cm in depth based on the drainage canal system and cross section which are set as above is given in Fig. 5-2-23. It is added that this figure has been modified from Fig. 5-2-19 by picking up the areas of more than 30 cm in depth.

Fig. 5-2-23 Geographical Distribution of Inundation  
(Case 1-2-2, Maximum Depth of Inundation Over 30 cm)

#### 5.2.5 Future site survey and analysis

In this year's study of drainage plan, primarily the drainage system was studied based on simulation analyses using the mathematical models, and the drainage canal system and cross section of the drainage canal which are considered to be optimum for the project area were outlined.

Though the conditions for the mathematical models are set according to the results of surveys performed in the 1st and 2nd years, it is preferable that these be verified or adjusted as necessary by the meteorology and hydrology of which observation has been underway for higher accuracy of simulations, and thus the drainage effect is expected to be clarified further.

For this purpose, the following surveys and analyses are required on top of those above in the 3rd year.

##### (1) Data for rainfall

Though the estimated design rainfall has been set based on the data by Yacyreta Observatory of Department of Meteorology, Ministry of National Defence, it is necessary to cover such extensive project area that the analyses be performed thoroughly using the data obtained by 3 observatories newly located by this survey team as well as the data by the Yacyreta Public Corporation, and that depending on the condition and when required the rainfall characteristics be further clarified for each rainfall runoff block using the data by suitable observatories.

##### (2) Data for discharge of rivers

Though 3 cases for the rainfall losses, coefficient of roughness, base flow, etc. were set by analyses in the work to outline this plan, it is necessary to analyze the discharge more exactly that collection and analyses of data for water levels of rivers of which collection has been commenced by auto-level gauges newly set by this survey team and the data for discharge being observed by Yacyreta Public Corporation, be proceeded further.

##### (3) Finalizing of drainage plan and verifying of effect

Based on surveys and analyses as above, the set conditions of mathematical models are verified and adjusted as and when required, and simulations are performed so as to finalize the plan, and particularly, effect of drainage work is clarified by estimated inundation distribution, depth of inundation, and hours of inundation.

### 5.3 Farm Land Development Plan

#### 5.3.1 On-farm plan

##### (1) Basic policy on-farm plan

This clause deals with on-farm plan, terminal irrigation and drainage canal, farm-road and pasture-fence.

In cultivation plan of this project area, rotation of wheat and soybean, dairy farming and rotation of paddy rice and pasturing are dealt with as key crops.

Therefore, it is supposed that on-farm plan is divided into 2 types, paddy field requiring irrigation canal, and upland field and grassland requiring no irrigation canal, because paddy rice needs irrigation farming. For upland field cultivation of labor intensive crops, namely irrigation plan is considered, however, it is examined by coordinating farming plan, cultivation plan etc. at the following year.

For farm road, upland field and grassland do not need banking specially, it can be easily determined by individual cultivation plan at actual farming stage.

As especially farm block is the most important in on-farm plan, it is determined considering local farming conditions, the present geographical features, irrigation plan and conditions of farming scale studied afterward, etc.

Soil in farm block is not removed in principle.

Differences among plans for paddy field as rotation area with pasture, for upland field as rotation area of wheat and soybean, and grassland in dairy farming area are described in individual clauses.

##### (2) Farm land consolidation

###### 1) Farm block

Farm block is examined on the base of circumstances of existing paddy rice farm, local geographical features and plan of irrigation, cultivation, farming and settlement determined in this master plan.

Study on the existing paddy rice farm was made as to the Bolf farm located in this project area and the Pappalardo farm near Asuncion.

The Bolf farm is managed by the standard size of 800 m × 800 m block,

however, farmers tend to reduce size of block for convenience of carrying out of farm products, according to hearing investigation. Moreover, in the Pappalardo farm, block previously 400 m × 2,500 m has been readjusted to 200 m × 2,500 m at present by the reasons of easy water control and carrying out of farm products.

The present topography may not affect the determination of farm block scale, as the present topography is so flat that the slope is mostly under 1/3,000 and partially 1/1,000, also field block and levee block are formed in farm block.

From a viewpoint of irrigation plan, farming block cannot be enlarged extremely because of continuous irrigation method.

On the base of cultivation and settlement plan, farming plan proposes various classes as farming scale per farmer. In the proposal, managing scale doubles by integral number of 25 ha, therefore it is the basic area of a farm block. For the shape of farm block, square is favourable from a viewpoint of field area.

Japanese data indicates that farm irrigation ditch is limited to 600 m long, and longer one causes occurrence of irregular water distribution and interfere with farming. Moreover, the required days for irrigation at peak time is limited to approximately 5 days.

Moreover, in survey on existing paddy rice culture farm, as the Pappalardo farm is far from this project area and its geographical grade is rather steep, it may be possible to irrigate relatively long farm block. Therefore, this plan lays emphasize on data of the Bolf farm existing in the project area.

The standard farm block accordingly is determined to be square 500 m × 500 m as shown in Fig. 5-3-1.

The terminal irrigation and drainage system of paddy field can be corresponded by the terminal irrigation and drainage plan described below.

This farm block shape and size apply upland field and grassland. Farm block is divided into field blocks or lots by levee depending upon cultivating crops, which are made at farming stages every year.

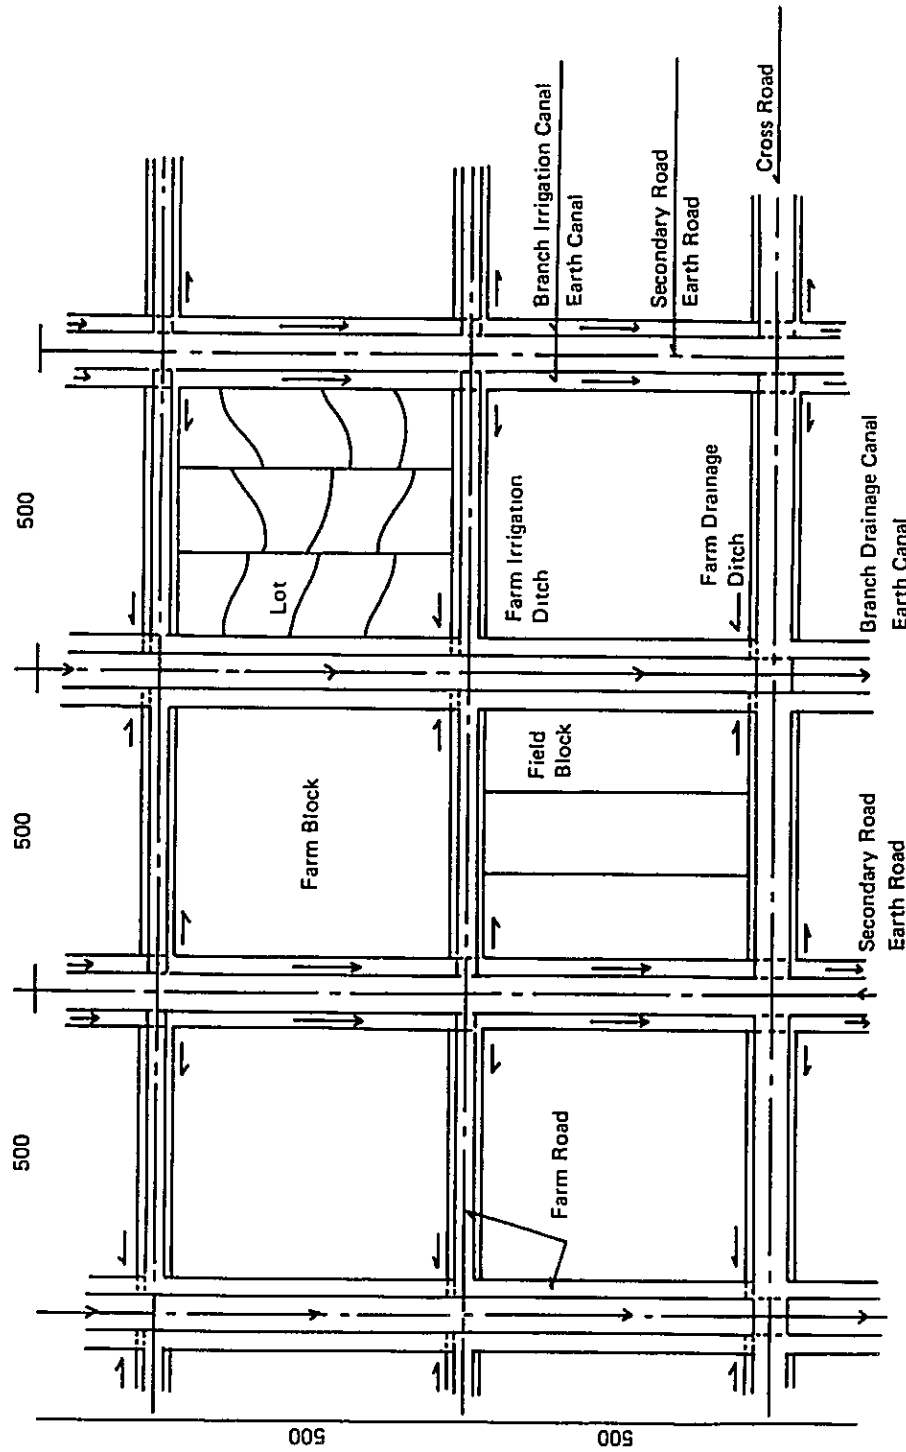

Fig. 5-3-1 Layout of On-farm Plan (Unit: m)

## 2) Terminal irrigation canal

The terminal irrigation canal should be planned for paddy field, which consists of branch irrigation canals and farm irrigation ditches.

Branch canal takes in water from trunk or main irrigation canal through intake gate, and distribute water to ditches adjacent to farm block through both sides of secondary road laid out beside farm block.

Branch irrigation canal, becoming economical by decreasing cross points with secondary road, should be laid out along both sides of secondary road shown in Fig. 5-3-1, at 2 farm blocks interval, namely 1 km interval parallel each other.

As shown in Fig. 5-3-1, farm irrigation is laid out at upstream side of farm block, and water distributed from branch irrigation canal flows in through inlet of levee of paddy field.

The structure is unlined canal and cross point with road is closed conduit. Terminal irrigation canal, especially farm irrigation ditches are reformed before irrigating every year.

The designed cross section, calculated by initial inundation within 6 days as shown in Table 5-3-1, is 1.5 m in bottom width and 0.3 m in water depth for ditch, and 6.0 m in bottom width and 0.5 m in water depth for branch irrigation canal as shown in Fig. 5-3-2.

Density, site area, control area, etc. of terminal irrigation canal in model block are described in Table 5-3-2.

## 3) Terminal drainage canal

As terminal drainage canal, branch drainage canal and farm drainage ditch for paddy field are planned.

Farm drainage ditch, as shown in Fig. 5-3-1 is laid out at downstream side of each farm block, and water flowed in from paddy field through outlet of levee flows down to branch drainage canal through this farm drainage ditch.

Branch drainage canal introduces water flowed in from farm drainage ditch to main drainage canal, which is laid out between farm roads at the rate of 1 canal every 2 blocks, namely at intervals of 1 km, as shown in Fig. 5-3-1.

The structure is unlined canal. The cross point with road is

divided into 2 types, cross of secondary road (crossing road) and branch drainage canal, and cross of farm drainage ditch and farm road. For the former, closed conduit or box culvert is laid out depending on scale, and for the later closed conduit or gangplank.

The designed cross section, calculated on the base of  $0.5 \text{ m}^3/\text{sec}/\text{km}^2$  given after drainage simulation as shown in Table 5-3-1, is 1.0 m in bottom width and 0.4 m in water depth for farm drainage ditch, and 6.0 m in bottom width and 0.9 m in water depth for branch drainage canal as shown in Fig. 5-3-2.

This cross section is rather wider than the section excluding 2 years probability rainfall within 2 days, and terminal drainage canal for paddy field, upland field and grassland is planned in same idea as it is recognized that upland crop can be introduced to the Area A by results of drainage simulation. The Area A should be examined further by results of detail analysis based on data collected by new investigation on drainage plan at the following year, as it is required to enlarge canal section partially in the Area A.

Density, site area, control area etc of terminal drainage canal in model block are described in Table 5-3-2.

| Facilities              | Control area (ha) | Unit flow (l/s/ha) | Flow (m <sup>3</sup> /s) | Bottom width (m) | Water depth (m) | Flow velocity (m/s) | Allowable flow (m <sup>3</sup> /s) |
|-------------------------|-------------------|--------------------|--------------------------|------------------|-----------------|---------------------|------------------------------------|
| Branch irrigation canal | 246.2             | 3.20               | 0.79                     | 6.0              | 0.5             | 0.27                | 0.92                               |
| Farm irrigation ditch   | 25.0              | 3.20               | 0.08                     | 1.5              | 0.3             | 0.18                | 0.10                               |
| Branch drainage canal   | 554.0             | 5.00               | 2.77                     | 6.0              | 0.9             | 0.38                | 2.78                               |
| Farm drainage ditch     | 25.0              | 5.00               | 0.13                     | 1.0              | 0.4             | 0.20                | 0.13                               |

- Requirement
1. Canal cross section is shown below.
  2. Longitudinal slope of channel is  $1/3,000 \sim 1/7,000$  based on the present condition.
  3. For calculation of discharge, Manning's formula is used.
  4. Coefficient of roughness ( $n$ ) is 0.025 for earth canal.
  5. On-farm irrigation water requirement is estimated by peak water requirement of 22.1 mm/day basing on irrigation plan.
  6. On-farm drainage discharge is estimated by 5.0 l/s/ha basing on drainage plan.

#### 4) Farm road

Farm road, as shown in Fig. 5-3-1 is laid out at 3 sides of farm block boundary except side of branch irrigation canal, namely along farm ditch, branch drainage canal and farm drainage ditch.

This road is used for farming on farm block such as rotary, temporary parking space etc. of large size machine. For paddy field, water level of the adjacent farm ditch and farm block should be considered.

Road section, therefore is earth road with 6.0 m in width and 0.4 m in banking height. For banking, earth excavated from drainage canal etc. is used.

For upland field and grassland, banking is not required and only levelling is performed simultaneously with treatment for prevegetation.

#### 5) Pasture-fence

Pasture-fence is provided to protect cultivating crops from grazing cattle and to prevent cattle from escaping. Particularly rotational paddy field with pasture and pasture is divided into each farm block by pasture-fence.

As shown in Fig. 5-3-3, the structure consists of wooden pile, thin wire and barbed wire. Stake is laid out at 5 m interval, and club is laid out at 2 points (1.67 m interval) between stakes. The height is 1.2 m and totally 4 wires are stretched, middle 2 wires are barbed wire and the top and bottom are thin wires.

For fixture of wires, as shown in Fig. 5-3-3, wire is inserted in a hole of stake or club and wound round fence wire. The gate is simple gate.

Fence is provided at on-farm side of branch canal, downstream side of farm drainage ditch and both sides of branch drainage canal.

Density of field fence is shown in Fig. 5-3-2.

Fig. 5-3-5 Layout of Main and Connecting On-farm Structure

### 5.3.2 Road plan

#### (1) Basic policy for road plan

For lay out of road route, in addition to natural conditions of profitable area, layout of national and local roads, utilization possibility, density etc., particularly layout of villages and farming facilities should be considered synthetically, as it forms a link of the chain of the agricultural development. Moreover, it is required to make the most effective plan after defining necessity, propriety and utilization form of the road from a viewpoint of purpose of transportation of material and crops and facility management.

In this plan, road is divided into trunk road, main road, secondary road and operation/maintenance road, and the layout and structure suitable for the function are planned.

Trunk road is connecting the adjacent cities and villages, while secondary road is adjacent to farm block and aimed at transportation of materials and farm products. Main road is connecting these trunk road and secondary road, and supports the function of trunk road.

The structure, particularly width should be planned so that vehicles runs safety and farm work is performed smoothly, considering farm mechanization plan in the light of existing roads.

Propriety of layout of road route from the standpoint of agricultural management is examined further together with plans concerned.

#### (2) Road consolidation

##### 1) Trunk road

##### a. Route system

According to the function of trunk road, roads connecting the project area circularly and crossing the area from the south to the north are laid out.

As existing roads of the adjacent area to the project area, local road Ayolas-San Cosme Road and Yabebyry-Ayolas Road along the southern boundary, local road Yabebyry-San Ignacio Road along the western boundary, local road Ayolas-Santiago Road running at the central area from the north to the south and Access Road (1-B) of the Yacyreta Dam are been provided.

Among these roads, Access Road (1-B) is asphalt pavement and still discharge its function.

Ayolas-San Cosme Road, Yabebyry-Ayolas Road and Yabebyry-San Ignacio Road are improved into a trunk road.

Ayolas-San Cosme Road and Yabebyry-Ayolas Road, however will be reconstructed as access road in the Yacyreta Dam Project, and adjusted when the plan is programmed.

As shown in Fig. 5-3-6, trunk roads running at the center of the western part and the eastern part from the south to the north, and at the northern project area from the west to the east are newly provided.

These trunk roads are laid out along trunk irrigation canal or main irrigation or drainage canal, and discharge the function of maintenance of these canals in addition to its original function.

#### b. Structure and cross section

As shown in Fig. 5-3-7, the road cross section is 15.0 m in total width, 10.0 m in effective width and 1.0 m in banking height so that large size trailer for transportation of materials and farm products can run frequently.

The road is paved with asphalt, gravel and crushed stone.

For banking, earth excavated from the adjacent drainage canal is used, and compacted by bulldozer or tire roller.

The total length, site area and density of trunk road are shown in Table 5-3-3.

At the crossing point of trunk road and trunk or main irrigation or drainage canal, bridge is provided.

Fig. 5-3-7 Trunk Road Standard Section (Unit: m)

## 2) Main road

### a. Route system

Main road, connecting trunk road to secondary road, is aimed at the supporting function of trunk road.

Moreover, main road is laid out along trunk or main irrigation or drainage canal and discharges the function of maintenance of these irrigation and drainage canal.

Main road is laid out as shown in Fig. 5-3-6 and all are newly provided.

### b. Structure and cross section

As shown in Fig. 5-3-8, the structure is 10.0 m in total width 7.0 m in effective width and 1.0 m in banking height so that large farming machine and large size trailer can pass each other.

The road is paved with gravel, crushed stone and sand.

For banking, earth excavated from the adjacent drainage canal is used, and compacted by bulldozer or tire roller.

The total length, site area and density of main road are shown in Table 5-3-4.

\* Whole area 152,300 ha

### 3) Secondary road and cross road

#### a. Route system

Secondary road, connecting main road to each farm block, is laid out parallel each other along branch drainage canal at the rate of 1 road every 2 blocks, namely at intervals of 1 km.

Moreover, secondary class road is laid out along trunk or main irrigation or drainage canal at the side which no road is provided and towards the direction crossing secondary road within block at the rate of 1 road every about 3 km.

This secondary class road is specially termed cross road.

#### b. Structure and cross section

The structure is 8.0 m in total width and 6.0 m in effective width as shown in Fig. 5-3-9 so that large size trailer and large farming machine can pass. The banking height is fixed to be 0.5 m considering approach of farming machine and water level of the adjacent branch irrigation canal, and discharges the function as side bank of the canal.

For banking, earth excavated from the adjacent drainage canal is used, and compacted by bulldozer or tire roller.

The road is paved with gravel where there is a fear of weakening at raining.

The total length, site area etc. of secondary road and cross road are shown in Table 5-3-2 and Table 5-3-5.

### 4) Operation and maintenance road

#### a. Route system

This road, aimed at management of irrigation or drainage canal, is laid out along trunk or main irrigation or drainage canal not running parallel to trunk or main road.

#### b. Structure and cross section

The structure and cross section are same as secondary road.

The total length and site area of this road are shown in Table 5-3-5.

**CHAPTER 6**  
**LAND USE PLAN AND OTHERS**

## 6.1 Land Utilization Plan

### 6.1.1 Basic policy for land utilization plan

The main objective of this project is to achieve the integrated agricultural development of a vast extent of unused and unvalued land spreading along the Parana River. As expounded in Chapter 2, this project area is limited in productivity considerably because of undesirable topological features. Accordingly, no increase of productivity would be prospected under present conditions.

Three activities written below will consequently contribute to promoting utilization of the land and, as a result, further development of local economy.

To improve agricultural infrastructure of drainage canal and road and etc.

To improve land productivity by using water which will be available as a result of the construction of the Yacyreta Dam for irrigation.

To increase overall farm production on the principle of raising the right product on the right place.

#### (1) The existing conditions and problems of the area

##### 1) Natural disaster

###### ① Rainfall and drainage

The project area has a little high annual rainfall of 1,500 mm on the average, the monthly average ranging from 90 to 160 mm, with the average number of from 5 to 8 rainy days in a month. Since rainfall is sufficient in this area, there is no limiting factor of rain shortage on agriculture.

From this fact, it is quite reasonable to say that the idea of constructing an irrigation system in this area is no requisite matter unless certain special farm products are to be raised.

However, natural drainage function is extremely poor at some places in this area. There will occur some inundation or areas locally if rain falls because 10 year's daily probability is 164.4 mm/day.

② Temperature

The area is 21°C in annual average. Average maximum and minimum temperature are 26.8°C, 15.9°C, respectively, which means mild climate very suitable for farming.

③ Effects of wind

In this area, the wind blows at an monthly average velocity ranging from 2.5 to 4 meters/sec, which is below 5 meters/sec, with rare occurrence of frosts. Consequently, it is hardly necessary to have windbreaks forest in this area.

2) Soil conditions

① Farm land conservation

The project area are features a low flat land with a overall gentle gradient, so that rainfall is unlikely to result in water erosion.

Since the soil mixes non-caking earth such as Regosols, care should be exerted in the design of an aqueduct or the like so that erosion will not occur.

② The bearing capacity of the soil

The area shows from 2.2 to 20.1 in the bearing capacity of the solid (with the average of 5.9 as measured by the Yamanaka hardness meter) except for some parts of swamps. With improvement of drainage, the soil will be hard enough for farm machinery to move about on it without sinking.

③ Conservation of soil fertility

The project area is relatively poor in natural fertility as compared with hilly land Furvisols. Because of this, soil fertility conservation measures will have to be maintained. Application of green manure and rotation of paddy field and grazing land are recommended as effective to this aim.

3) Conservation of forest

The forest presently dominates 7% of the total area of the project area and consists of natural forest. There are very few marketable trees. These forests should be left intact for conservation of natural environment.

4) Enhancement of land use

The project area comprises for the most a vast extent of swamp except for paddy fields developed in the gently sloped alluvial fans and small arable land scattered in the natural forests. It can be said that ways of farming in which that sections of land which have good drainage condition are used as grazing land stand contrary to good land use.

5) Land possession and land utilization

As already expounded in Land Possession, ownership of land within the project area is possessed by a very small number of big landowners, the majority of whose land are fenced up. These fenced land contain vast areas of swamps with low land use.

Although settlers have inhabited the south part of the project area, development is slow in progress in those sections for poor-drainage topology in this part. A development plan should be designed such as to treat those swamps according to their particular conditions and size.

(2) Basic policies in the formulation of outline of the land utilization project

In the formulation of outline for land utilization plan, rational use of land resources, farming on the principle of raising the right crop on the right place, farm land preservation, and enhancement of the use of land should be emphasized as the objectives of the plan, and to facilitate the achievement of these objectives, the following policies should be set up.

1) The scope of the project area

The project area is confined to that area of unused and unvalued area which will be able to make use of irrigation water to be made available as a result of the construction of the Yacyreta Dam.

2) Techniques for the plan

The project area is classified by use into land for agriculture (paddy field with irrigation, upland field, grazing land), drainage, traffic, residence, and facilities for agricultural processing by overall coordination of results of land classification, proposed drainage projects, land consolidation plans, and basic policies recommended by the Paraguay government.

### 6.1.2 Formulation of outline of the scope of the project area

The scope of the project area is generally demarcated as follows according to the policies in the land utilization plan.

(Refer to Fig. 6-1-1 Plan of the project area)

(1) The boundary bordered on the hilly land on the north

Hilly land more than 90 meters in elevation features the land and is highly advanced in effective land use because of good drainage conditions. The project area is demarcated, as a rule, along the elevation line of 90 meters. Where the contour line of 90 meters recedes in protrusion as there are valleys or dales, the area is demarcated within the scope of about 2 km as a result of considered compromise between good natural drainage and the geographical configuration of the area.

(2) The western boundary

From the standpoints of convenience of transportation and water catchment, the demarcation line is drawn along the San Ignacio road on the west.

(3) The southern boundary

1) Between Ayolas and Yabebyry

The area along the Parana River falls here/in this district falls/within the flood zone of the main stream. The demarcation line follows the existing road running between Ayolas and Yabebyry as a result of consideration of the distribution of urbans and settlements.

2) The settled area

There is a settled area of 3,300 ha along the Ayolas-Yabebyry road. Although this area is being developed, it needs systematic improvement of drainage at places because of its topological condition. It was decided to include settled area within the scope of the present land utilization plan. It was agreed with the Paraguay authorities concerned to treat this settled area as a special district for political reasons which included the problem of allotment of project cost.

3) Between Ayolas and the Yacyreta Dam right bank

The demarcation line is drawn to follow the route Access 1 and the Sanchago-Ayolas road that branches off from it. Along this road
