1. Construction Material Sources Around Beris Dam Site

SPECIAL ABBREVIATIONS

Unit of Measure

Prefix M: Mega- = 10^6

 $K : Kilo- = 10^3$

C : centi = 1/100

Force N: Newton = 1 kg·m/s^2

Pressure Pa: Pascal = 1 N/m^2

Special Conversion Factors

 $1 \text{ kgf/m}^2 = 9.80665 \text{ Pa}$

 $1 \text{ kPa} = 1/98 \text{ kgf/cm}^2$

 $1 N = 10^5 dyn$

1. INTRODUCTION

The object of a construction material survey for the feasibility study of the Beris dam is; (1) to find adequate sources of fill materials and concrete aggregate, (2) to estimate available quantity, and (3) to evaluate quality of the materials for the Beris dam including the main and saddle dams and their appurtenant structures.

Field investigation was carried out for the period from December 1983 to February 1984 involving site reconnaissance and sampling of materials. The laboratory tests for sampled materials were undertaken by the Government of Malaysia.

During the survey period, three alternative quarry sites, two alternative borrow pits for cohesive soil (impervious core) materials and four possible borrow pits for sand and gravel (filter and concrete aggregate) were investigated.

The requirement of construction materials is set out in Section 2, and proposed material sources are described in Section 3. Section 4 itemizes the laboratory tests executed in this survey. Mechanical properties of the residual soils are assessed on the basis of the laboratory test results in Section 5, while the properties of sand, gravel and rock are evaluated in Section 6. Basic zoning design and applied design values of a rockfill dam are studied in Section 7.

2. CONSTRUCTION MATERIAL REQUIREMENT

As introduced in Main Report, the Beris dam comprises the main dam with height 41 m and volume about $60,000~\text{m}^3$ as a concrete gravity dam, and also saddle dam with height 28 m and volume of about $120,000~\text{m}^3$ as a rockfill dam.

The required volume of construction materials as-built condition is preliminarily estimated on the basis of the dam design, and it is shown in Table 1.

CONSTRUCTION MATERIAL SOURCES

3.1 General

The sources of construction materials are classified into the following three setouts:

(1) Quarry site: rock for fill dam and masonry, fine and coarse aggregates for concrete dam and other concrete structures, and filter and drain materials for

fill dam and other embankments.

- (2) Borrow pit for cohesive soil; impervious core material for fill dam, earth materials for other embankment and backfill.
- (3) Borrow pit for sand and gravel; filter and drain materials for fill dam, fine and coarse aggregates for concrete dam and other structures.

Plate 1 shows the location of alternative and possible borrow pits for cohesive soils, sand and gravel, and quarry sites. Quality and available quantity of these material sources are preliminarily evaluated and summarized in Tables 2 and 3.

3.2 Cohesive Soils

No predominant deposit of alluvial soil was found around the proposed Beris damsite. The cohesive soils in the project area are mostly composed of residual soils, which are originated from sandstone and/or shale.

Two prospective borrow pits of Bl and B2 are identified as alternative material sources for an impervious core of the saddle dam and other embankments. The Bl borrow pit is located on the right bank along the Beris river, 0.2 to 1.0 km northwest (downstream) of the main damsite. The B2 borrow pit is also on the right bank, and is 0.3 to 1.1 km northwest of the saddle damsite.

The soils of these borrow pits are composed of reddish and lateritic clays. They are classified into the soils of shale origins and sandstone origins. The soils in Bl and B2 borrow pits are mainly originated from shale and sandstone, respectively. Both soils are sufficiently impervious material for core zone of rockfill dam. However, regarding the trafficability and shear strength, borrow pit B2 is judged to be better than borrow pit B1 based on the laboratory test results.

The available quantity of the Bl and B2 sites is estimated around $400,000~\text{m}^3$ and $300,000~\text{m}^3$, respectively. The thickness of usable soil layer is assumed to be 3 m. The depth of layer is not constant but varies between 2 m and 5 m from the ground surface. The ground water was not observed within a depth of 5 m.

3.3 Sand and Gravel

No major terrace deposit of sand and gravel is found along the Beris and Muda rivers within a reasonable distance from the proposed damsite. On the other hand, minor deposite of sand and gravel are observed in the river channels of the Beris river upstream of the damsite and in the Muda river upstream of the confluence of the Beris river. These deposits are mostly submerged in the river channel even in the dry season.

Four major deposits of SG1, SG2, SG3 and SG4 are identified as alternative sources for concrete aggregates, and filter and transition materials of fill dam. In the four sites, the SG2 and SG4 sites are estimated to have relatively large quantity.

In the Beris river, medium and coarse sands are deposited in the river channel while fine sands are identified on both banks. The thickness of sand layer is about 1 m. Some sand layers consist of very uniform gravel of less than 10 mm. There lies a gravel layer below the sand layer in places. The thickness of gravel layer could not be measured because of river water.

The deposits in the Muda river are larger in particle size than those of the Beris river. The thickness of the layer is around 2 m. The sand layers are mostly composed of medium and coarse sands.

The available quantity of SG1, SG2, SG3 and SG4 is approximately estimated at $3,000~\text{m}^3$, $10,000~\text{m}^3$, $1,000~\text{m}^3$ and $10,000~\text{m}^3$, respectively. However, the required quantity of sand and gravel materials is much larger than the available one, therefore most of concrete aggregates, and filter and drain materials accordingly should be produced by a crushing plant from quarried rock.

3.4 Quarry

In Part 1 study, Quarry site Q1 was proposed on the basis of the results of geological surface exploration. However, the subsurface exploration results by using boring machine indicates that the rock material in Q1 site is inadequate because the quality of rocks is deemed worse for construction materials. Consequently, Q2 and Q3 sites were investigated additionally.

According to the geological investigation, it could be judged that the Q2 site is the best among the three sites in terms of quality of rock, available quantity of fresh rock and cost effectiveness. The geological features of these quarry sites are discussed in detail in Annex G "Engineering Geology".

The available quantity of fresh rock is estimated at $300-400 \times 10^3 \text{ m}^3$ for Q2 and $200 \times 10^3 \text{ m}^3$ for Q3 respectively.

4. LABORATORY TEST SCHEDULE AND TESTING METHOD

The principal object of the laboratory tests is to evaluate the physical, chemical and engineering properties of the prospective fill materials and concrete aggregates in and around the Beris damsite in the stage of feasibility study.

The laboratory test items and their sample numbers undertaken in this study are listed in Tables 4 and 5.

The head of the sample number denotes the number of the test pits or bore holes. The location of test pits is shown in Fig. 1.

4.1 Cohesive Soils

All cohesive soils sampled from the test pits, gradation analysis (particle size distribution), specific gravity test, field moisture content test, Atterberg's limits test were done as a series of physical and chemical properties tests. The analyses of clay mineral content and soluble salt content were done for the selected 5 samples.

As for mechanical property test for moisture-density relation using a rammer, the permeability test with falling head, the triaxial compression test (CU; consolidated undrained) with sample diameter of 38 mm, the consolidation test with sample diameter of 60 mm, and the swelling test with sample diameter of 60 mm were done for the selected samples. The Proctor compaction test was done with variable compaction energy of the standard compaction, twice and three times of the standard compaction energy (say 1E, 2E and 3E).

The samples for the permeability, triaxial compression, consolidation and swelling tests were compacted under optimum moisture content (OMC) with variable compaction energy (1E, 2E & 3E) in order to figure out the relation among mechanical properties, compaction energy and compaction method. The triaxial compression tests were executed under consolidated and undrained condition after the samples were saturated, consolidated and the porewater pressure was also measured so as to obtain the effective-stress parameters.

The sieve analysis was done under water washing. A same naturally dried sample was used repeatedly in process of getting the optimum moisture content (OMC) for time saving because the effect of water sensitivity was considered being negligible.

The tests performed in the DID laboratory were according to the British Standard, BS1377-1975.

4.2 Sand, Gravel and Quarried Rock

For sand and gravel, particle size distribution and specific gravity were measured. Organic content was measured for sand only.

For quarried rock, specific gravity test, bulk density test, moisture content test, water absorption test, mechanical durability test and compressive strength test were done.

5. SOIL MECHANICAL PROPERTIES OF RESIDUAL SOILS

5.1 Physical and Chemical Properties

The cohesive soils in the project area are mostly composed of residual soils which are the product of rock weathering accumulated in place. The parent rock of the residual soils are considered being shale, sandstone and alternation of shale and sandstone which are the predominant rocks formations in the project area. The particle size distribution differs significantly among some samples even if taken from the same area. The particle size distribution depends on the degree of weathering and the matrix of the parent rock. It is impossible to clarify the main factors which cause the variation of particle size distribution, but it can be inferred that the sand content may be high in the area having predominant sandstone formation (BR5, BR7 and BR8) while the silt and clay content may be high in the area having the predominant shale formation (BR1, BR3 and BR4).

The results of physical and chemical property tests of the residual soils are summarized in Tables 6 and 7.

(1) Particle size distribution, consistency and the Unified Soil Classification System

The content of silt and clay (smaller than 0.06 mm) is very high, i.e., 65 to 85% for shale originated soil and 34 to 58% for sandstone originated soil. The content of sand and gravel (larger than 0.06 mm) are 15 to 35% for shale originated soil and 42 to 66% for sandstone originated soil respectively. The maximum size of gravel ranges from 2 to 10 mm.

The particle size distributions of the residual soils are shown in Figs. 2 to 4. The resulting high content of fines and comparatively poorly graded shale originated soils imply a low compacted density and indicate proneness to cracking after being compacted.

The liquid limit (WL) ranges 36 to 98%, with an average of 81.8% for shale originated soil and with an average of 53.8% for sandstone originated soil, respectively.

The plasticity index (Ip) ranges 14 to 66%, with an average of 49.1% for shale originated soil and with an average of 25.8% for sandstone originated soils respectively.

The soils of shale origins are reddish and lateritic silts and clays and they are classified to be MH or CH in the Unified Soil Classification System (See Table 8 and Ref. H 2) as shown in Fig. 5. They also indicate the medium to high plastic soils with high resistibility to piping for impervious core materials. Whereas, the soils of sandstone origins are classified to be SM or CL as shown in Table 8 and Fig. 5, i.e., silty sands and sandy clays with low to medium plasticity.

(2) Specific gravity, organic content and pH

The specific gravity is in the range of 2.6 to 2.7. The organic content was not tested for cohesive soils because no organic substance was found by eye observation. The tests in Part 1 Study showed that the content was less than 1% (Ref. H 1).

The value of pH is 4.5 to 4.9 and all the soils are considered to be slightly acid.

(3) Dry density, OMC and field moisture content

Compaction tests on soil samples are carried out in accordance with BS 1377: Test 12 (standard compaction test). Furthermore, the compaction energy is changed in a range from the standard compaction energy (6.075 kg/cm² say 1E) to twice and three times of the standard compaction energy (say 2E and 3E). The results of the compaction test are shown in Figs. 7 to 9 and are summarized in Table 21.

Table 21 shows that compacted dry densities of shale originated soils (BR1, BR3 and BR4) are lower than those of sandstone originated soils (BR5, BR7 and BR8).

The maximum dry densities of shale originated soils at 1E are 1.4 to $1.62~{\rm Mg/m^3}$, with an average of $1.50~{\rm Mg/m^3}$, whereas those of sandstone originated soils are $1.64~{\rm to}~1.83~{\rm Mg/m^3}$ with an average of $1.73~{\rm Mg/m^3}$. This is due to the larger percentages of silts and clays, and the poorly graded materials as well as the high moisture content of shale originated soils.

The optimum moisture content (OMC) decreases (moves to dry side) and the maximum dry density increases in proportion to the increase of compaction energy from 1E to 2E, but there is little change in the range from 2E to 3E. These facts imply that the over-compaction phenomenon occurred at 3E compaction energy.

The field moisture content of shale originated soils is 21 to 29% with an average of 26.0%; comparatively high. That of sandstone originated soils is 14 to 24% with an average of 18.2%.

Since the field moisture content in dry season is slightly wetter (2 to 6%) than the OMC at 2E, which is the recommendable compaction energy during the construction stage, the field moisture content at the beginning and end of dry season is inferred to be on wetter side, the material is required to dry out artificially to around the OMC to achieve the best mechanical properties, of compacted soil, imperviousness and strength as well as trafficability.

(4) Clay mineral content

The test results of analysis of clay mineral content are shown in Table 9. The loss on ignition is 6.9 to 10.6%. Silica (SiO₂) and Alumina (Al₂O₃) are major minerals, and their contents are 77.6 to 83.9% and 6.9

to 11.0% respectively. Calcium Oxide (CaO), Magnesium Oxide (MgO), Potassium Oxide (K_2O) and Sodium Oxide (Na₂O) are contained but to quite a minor extent.

The composition of clay minerals was analyzed by a X-ray scanning machine with a Cu-target X-ray tube and a scintillation counter. The samples are dispersed in distilled water, treated with glycolate and heated at 550°C.

Only Kaolinite and trace amount of Illite are identified from the 5 samples as shown in Table 10. Some fine quartzs suspended with the clay fraction are also detected on the diffractograms. Since Halloysite and Montmorillonite are not identified, residual soils are evaluated to be relatively stable against chemical deterioration.

(5) Soluble salt content

The soluble salt content shown in Table 11 was measured in terms of Ca^{++} , Mg^{++} , K^{+} and Na^{+} to check dispersive character of the residual soils. The total soluble salt content is only less than 0.2% of the total clay mineral content (See Table 9).

According to the suggestion by J.L Sherard etc. (Ref. H 3), the amount of dissolved sodium relative to other salts in the porewater is the main factor determining whether a clay is dispersive or not. From the study shown in Fig. 6, the relation of porewater salts and dispersion of compacted samples indicates that the residual soils in the proposed borrow site are inferred to be non-dispersive.

5.2 Assessment of Mechanical Properties Required for Rolled Earth Dams

5.2.1 Mechanical properties of compacted soils

The permeability test, the triaxial compression test (CU), the consolidation test and the swelling test were done for the samples compacted with the standard compaction energy (IE) under OMC at first. On the basis of these test results, the following conclusions are reached:

(1) Trafficability

The trafficability of the residual soils, especially of shale originated soils will be inadequate, if the placement moisture content is in wet-side from OMC (IE).

According to the experience of the Feasibility Study of Reman Project, (Nov. 1983), the penetration resistance of residual soils in a cone penetration test of compacted samples ranged from 24 to 68 kg/cm² at OMC, indicating that the movement of heavy construction equipment, i.e., dump-tracks, on the embankment will not be hampered, however, it decreases to 8 to 19 kg/cm² at about 4% wet-side placement moisture from OMC; only the dozer-type equipment movable.

Judging from the comparatively high field moisture content, of shale originated soils in rainy season, some control of the placement moisture or the mixing method with the other coarse material, weathered sandstone or weathered congromerate, will be required, otherwise the embankment work will be restricted only during the dry season.

(2) Shear strength

The triaxial test (CU) was done for the specimen compacted with standard compaction energy (1E) under OMC, 2E and 3E. The test results are shown in Tables 12 - 14 and Figs. 13 - 22. In the effective stress condition of standard compaction energy, the cohesion (C') is $0.37 - 1.4 \text{ kg/cm}^2$ and the angle of internal friction (\emptyset ') is $17 - 26.5^{\circ}$. In the total stress condition the cohesion (Ccu) is $0.58 - 1.65 \text{ kg/cm}^2$ and the angle of internal friction (\emptyset cu) is $5 - 14^{\circ}$.

The cohesion is fairly high but the internal friction angle is low; accordingly, this material is evaluated to be inadequate for high homogeneous embankments which require high shear strength, but it can be used for the impervious core of the central-core type fill dams of several ten m in height.

(3) Permeability

The coefficient of permeability is in a range of 3.7 x 10^{-5} - 4.3 x 10^{-7} cm/sec if samples are compacted with the standard compaction energy under OMC (See Tables 6 & 7). It is considered that these residual soil are suitable for forming an impervious core.

(4) Compressibility and swelling

The consolidation test results are shown in Tables 15 - 19. The compressibility is estimated using the void ratio - consolidation pressure relationship shown in Figs. 10 - 12, and it is listed in Table 20.

The compressibility $(e_O - e_i)/(1 + e_O)$ under standard compaction energy is high of 5.5 - 6.9% under a loading pressure of 2 kg/cm², 8.2 - 9.1% under a loading pressure of 4 kg/cm² and 9.7 - 11.8% under a loading pressure of 6 kg/cm².

The measures to prevent large settlement are the sufficient compaction by heavy compactor (compaction energy 2E) and the mixing of coarse material as well as controlling of placement moisture by drying to the optimum moisture content.

The change in height due to swelling is 0.25-0.5% and the swelling pressure is $0.05-0.1~{\rm kg/cm^2}$. These are considered being rather low though the content of clay and silt is extremely high. The swelling process and its testing procedure are shown in Fig. 23.

5.2.2 Dry density - permeability - shear strength - compressibility relationship

The compaction energy was changed in the range from the standard compaction energy (say 1E) to three times of the standard compaction energy (say 3E) and the variation of the maximum dry density, the permeability, the shear strength parameters, the compressibility and the swelling were measured.

Figures 23 and 24, Tables 20, 21 and 22 shows the behaviour set out below:

- i) The optimum moisture content (OMC) decreases (moves to dry side) and accordingly the maximum dry density increases in proportion to the increase in compaction energy from 12 to 2E, but they do not change in the range from 2E to 3E (See also Figs. 7 9 and Table 21).
- ii) The permeability decreases remarkably with increase in compaction energy from 1E to 2E, but its change is insignificant if energy is increased from 2E to 3E. (See also Table 22).
- iii) The compressibility is improved by 0-3.9 to 0.7-5.0% in proportion to the increase of compaction energy from 1E to 2E and 3E (see Table 20).
- iv) The shear strength increases a little with the increase of compaction energy. (See Fig. 24)
- v) No major effect due to variation of compaction energy is observed in swelling. The increase in sample height due to swelling is 0.25 to 0.5% if an energy of 1E or 2E is applied, while it is 0.1 to 0.2% under 3E. (See Fig. 23)
 Further, the swelling pressure is very low of 0.05 to 0.1 kg/cm², soils may be regarded as non-swelling.

5.3 Conclusions and Recommendations

- i) Based on the field investigation and soil test results the proposed impervious soils are classified as shale originated soil and sandstone originated soil.
- ii) The sandstone originated soils (Borrow Pit B-2) are suitable for use as the impervious core material of the rockfill dams. However, the shale originated soils (Borrow Pit B-1) are unsuitable for the core material, because;

- a) The sandstone originated soils are classified to be SM-SC or CL, which are silty sands, clayey sands or sandy clays with low to medium plasticity. These soils have the engineering properties such as sufficient trafficability, imperviousness, shear strength, piping resistance, etc., and they can be used for the core material without mixing course material. Moisture content can be controlled easily at around OMC without special processing.
- b) The shale originated soils are classified to be CH or MH, which are inorganic clay of high plasticity or inorganic silt. These soils have the engineering properties such as insufficient trafficability in rainy season, low shear strength and poor workability (ease of moisture density control). Since the content of fine particle (0.06 mm under particle) is more than 65 to 85%, much shrinkage crack will occur.

According to the above conclusions on the basis of technical assessment of soil mechanical properties, only sandstone originated soil is recommended as an impervious core material of rockfill dam. Because, shale originated soil is difficult to use as a fill material without mixing with coarse material, mixing process is costly, and available quantity of sandstone originated soils is sufficient to meet the requirement. Consequently, Borrow Pit B-2 is recommended to develop for the core material source.

Prior to the development of Borrow Pit B-2, test trenching should be done to investigate the fluctuation of moisture content and particle size distribution of the sandstone originated soils. Excavation by using bull-dozer with ripper can be made effectively for these soils.

6. PROPERTIES OF SAND, GRAVEL AND ROCK

6.1 Sand and Gravel

The physical and chemical test results are summarized in Tables 23 and 24. The particle size distributions are shown in Figs. 25 and 26.

The samples are all submerged in river water and thus almost no clay and silt portion is contained. The particle size distribution is rather well graded. The maximum grain size is around 10 mm and sand particles (0.06 - 2 mm) accounts predominant portion (48 - 96%). These sand and gravel deposits are classified in the Unified Soil Classification System as:

SG1 : SW

SG2: GP, SW, SP (can be mixed easily)

SG3 : GP-SP

SG4 : SW

The specific gravity is 2.62 - 2.81 and the organic content is as low as 0.2 - 0.5%. The property of these materials is evaluated being good and resembles to that of the proposed quarry rock (see Section 6.2).

6.2 Rock

The specific gravity, the bulk density, the moisture content, the water absorption, the chemical durability and the compressive strength were measured for the rock core samples from the bore holes in the alternative quarry sites. These test results are shown in Table 25.

The apparent specific gravity is 2.68-2.73 (> 2.6). The oven-dried bulk density is 2.51-2.59. The moisture content is 0.2-0.5%. The water absorption is 0.4-0.8%. The weighted percentage loss by sodium sulphate is 1.5-4.2 (< 10%). The compressive strength is 124,700-187,450 kPa (1,272-1,813 kgf/cm²). These test results show that the rock quality of the tested specimens is adequate for concrete aggregates and rock embankment.

7. ZONING DESIGN OF ROCKFILL DAM

7.1 Design of Filter and Transition Zones

7.1.1 Filter design

A requirement of grain size distribution for the filter materials, which is specified in the Design Criteria for Dams (Japanese National Committee on Large Dams; Ref. H 4), is shown below:

- i) $(D_{15} \text{ Filter})/(D_{15} \text{ Core}) > 5$
- ii) (D₁₅ Filter)/(D₈₅ Core) < 5
- iii) It is desirable that gradation curve of filter materials is approximately parallel to that of the materials protected.
 - iv) If materials to be protected by filter contain coarse materials, (i) and (ii) shall be applied to the materials under 25 mm size.
 - v) Filter materials shall not be cohesive and not contain more than 5 percent fine passing the No. 200 (0.074 mm) sieve. If the materials to be protected are cohesive, these rules may be somewhat mitigated.

where,

D₁₅ Filter : 15% grain size of filter materials

D Core : 15% grain size of materials protected by filter

D Core : 85% grain size of materials protected

by filter

If these rules are applied to the sandstone originated soils of a grain size distribution of Borrow Pit B2 shown in Fig. 4, the 15% grain size of filter material is specified as follows:

- i) $(D_{15} \text{ Filter})/(D_{15} \text{ Core} = 0.0003 \text{ mm}) > 5$
 - ... $(D_{15} \text{ Filter}) > 0.0015 \text{ mm}$ and;
- ii) $(D_{15} \text{ Filter})/(D_{85} \text{ Core} = 4 \text{ mm}) < 5$
 - $(D_{15} \text{ Filter}) < 20 \text{ mm}$

According to the particle size distribution of sand in the prospective borrow area as shown in Figs. 25 and 26, all sands can be utilized as filter materials.

Fine concrete aggregate produced by a crushing plant from quarried rocks is also suitable for filter material, because the standard grain distribution of the fine aggregate satisfies the above-mentioned criteria.

To secure the safety of dam, the filter design will be prescribed with the above criteria strictly.

7.1.2 Transition zone between filter and rock zones

The two principal requirements for a transition zone are that it must be more pervious than the protected filter, and that it must be fine enough to prevent particles of the protected filter from washing away through its voids.

The requirement of grain size distribution for transition materials is also applied the Design Criteria for Dams described in Subsection 7.1.1.

7.2 Design Values

The construction materials of the saddle dam embankment are classified into 4 zones, namely an impervious core as zone 1, a filter as zone 2, a transition as zone 3 and a rock as zone 4 for zoning design and stability analysis of dam body. The design values for each zone are determined as shown in Fig. 27 and Table 26.

The values for the zones 2, 3 and 4 are not supported by any test results but are assumed on conservative side based on experiences under similar condition.

To confirm the assumed design values, additional investigations should be done in the detailed design stage. Future investigation is described in Section 8.

8. FUTURE INVESTIGATION

Additional construction material survey should be done in the detailed design stage to confirm the assumed design values and estimated quantities of the investigated materials in the feasibility study. Items and quantities for the future investigation are proposed as follows:

(1) Test pitting

Borrow pit B-2

3 test pits, $2.0 \text{ m} \times 2.0 \text{ m} \times 5 \text{ m}$ deep.

Sampling, 2 points per each pit.

(2) Test trenching

Borrow pit B-2

1 trench, 50 m long, depth up to the top of

weathered bedrock or 10 m deep.

Sampling, 3-5 points.

(3) Reconnaissance for additional sand and gravel borrow pit : Along the Beris river and the Muda river other than the investigated areas in the

feasibility study stage.

Sampling, 3-5 points.

(4) Sampling and laboratory test

Laboratory tests for disturbed soil samples, and sand and gravel samples shall be done to clarify the physical and mechanical properties such as grain size distribution, field moisture content, maximum dry density, shear strength, permeability tests, etc.

(5) Test embankment

Test embankment for impervious core material should be done to find out a suitable embankment method and obtain a useful data to establish technical specifications for construction materials.

Table 8 GROUP SYMBOLS AND DESCRIPTION OF UNIFIED SOIL CLASSIFICATION

Group Symbols	s Typical Names
GW	Well graded gravels, gravel-sand mixtures, little or no fines
GP	Poorly graded gravels, gravel-sand mixtures, little or no fines
GM	Silty gravels, poorly graded gravel-sand-silt mixtures
GC	Clayey gravels, poorly graded gravel-sand-clay mixtures
SW	Well graded sands, gravelly sands, little or no fines
SP	Poorly graded sands, gravelly sands, little or no fines
SM	Silty sands, poorly graded sand-silt mixtures
sc	Clayey sands, poorly graded sand-clay mixtures
ML	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands with slight plasticity
CL	Inorganic clays of low to medium plasticity, gravelly clays, sandy clays, silty clays, lean clays
OL	Organic silts and organic silt-clays of low plasticity
МН	Inorganic silts, micaceous or diatomaceous fine sandy or silty soils, elastic silts
СН	Inorganic clays of high plasticity, fat clays
ОН	Organic clays of medium to high plasticity
Pt	Peat and other highly organic soils
Remark:	Soils possessing characteristics of two groups are designated by combinations of symbols. For example, GW-GC, well graded gravel-sand mixture with clay binder.

Percent Sodium = $\frac{Na(100)}{Ca + Mg + Na + K}$

(all measured in milliequivalents per liter of saturation extract)

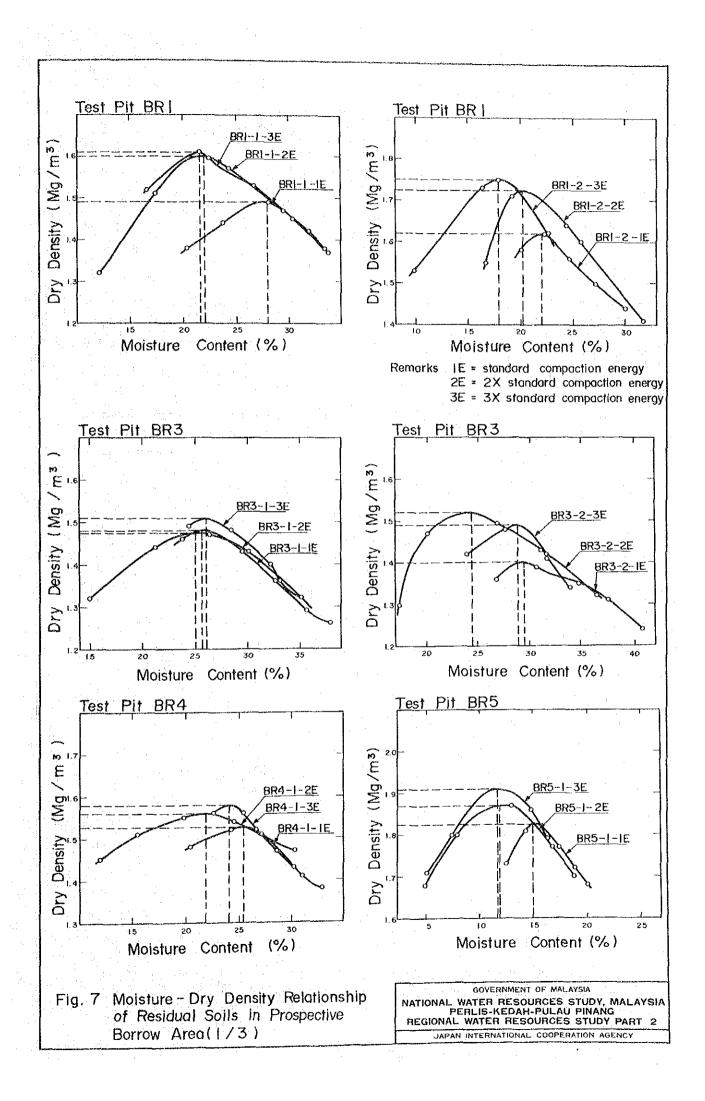

Total Dissolved Salts in Saturation Extract in Milllequivalents per Liter (TDS = Ca + Mq + Na + K)

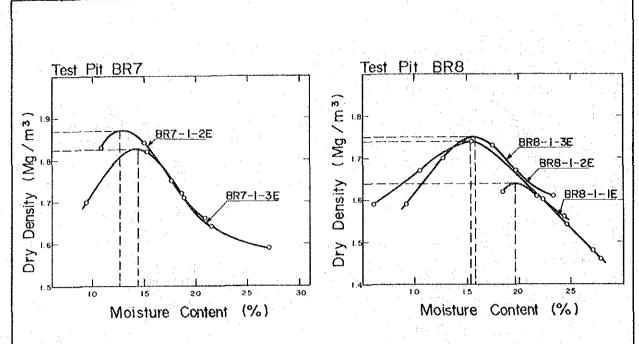

- Zone A. Much experience shows that damaged and failed dams all over the world have been constructed of these dispersive soils. Almost all soils are dispersive in the pinhole test.
- Zone B. The great majority of these soils are nondispersive.

 These are the soils generally considered "ordinary erosion resistant clays," but include silts of low plasticity (ML), also nondispersive. A small percentage of exceptional soils in Zone B erode in the pinhole test in exactly the same fashion as soils of Zone A, and some of these can be identified only by the pinhole test.
- Zone C. Soils in this group may range from dispersive to nondispersive. This group contains a few soils which give intermediate reaction in pinhole tests, with apparently colloidal erosion but at a very slow rate compared with soils of Zone A.
