11-A1　Dalcheon

The dam site is located on the Dal River approximately 9 km upstream from its confluence with the South Han River and about 6.5 km southwest of Chungju City.

The basement here is comprised of gneiss and schist and the dam site is situated where a granite mass has intruded both rocks.

The left bank forms a ridge consisting of granite. The edge of the ridge becomes a steep cliff which drops to the river. The top of the ridge is weathered for 3 to 5 m. The right bank is a gentle slope reaching to the river and since talus is only deposited thinly, there will be no problem. The river gradient in this vicinity is approximately 1/600 and there is a thick gravel layer deposited at the river bed.

Although there is no problem geologically inside the reservoir, the number of objects requiring compensation is very large. Farmers here are prosperous compared with those in upper reaches of the South Han River and there are many fertile paddies and fields, so that it is considered compensation for submerged areas will be a big problem.

This site is being contemplated from the necessity for flood control and water supply.
The road from Chungju City to the dam site is in comparatively good condition, though partial repairs will be necessary.

Since there are sand and gravel which are suitable as concrete aggregates upstream of the dam site, it is thought a concrete gravity-type dam would be suitable.

12-A3 Ganhyeon

The Ganhyeon Dam site is located approximately 25 km upstream along the Tam River which flows into the South Han River from the north and approximately 7 km northwest of Weonju City.

The river gradient in this vicinity is approximately 1/800 and relatively gen le, and the river flows southwest meandering widely until it merges to the South Han River.

Outcrops of quartz porphyry are seen at both banks of the dam site, and the river bed and both abutments are also quartz porphyry which is hard and dense so that the bedrock is good and there is no problem with the geology.

A saddle exists at the left bank with granite exposed at the reservoir side up to elevation of about 120 m, downstream from which a gentle slope consisting of weathered granite and talus deposits is developed. It is thought leakage from the reservoir will not be a problem at the planned high water level of 111.40 m.

Since there are many houses, paddies and fields in the vicinity of the end of the reservoir, detailed topographical surveys should be made hereafter including this vicinity and the number of objects of compensation investigated.
At the left bank downstream from the dam site and beyond 500 to 600 m upstream there are large quantities of sand and gravel on the river bed so that this site is favored with natural concrete materials of good quality.

DATE　　　FIG.

A - 79

The project site is located approximately 408 km up the Nakdong
River and about 20 km upstream from the end of the Andong Dam backwater.

The river gradient in this vicinity is around 1/480 and relatively
gentle.

The bed rock of the originally proposed dam site consists of
sedimentary rocks – alternations of sandstone and conglomerate.
The left bank is steeply sloped and outcrops can be seen, while at
the river bed the gravel layer is thin and thought to be 1 – 2 m.
Although it is thought there will be no special problem as a dam
foundation, slight loosening of the bedrock can be seen at the right
abutment and there is a possibility that deep excavation will be required.

An alternative site approximately 3 km downstream from the original
one can be considered. The downstream alternative site has talus at
the left bank and the deposit is estimated to be about 5 to 6 m in
thickness, while topographically, the site is wider compared with
the upstream original site. The geology is the same as that of the
upstream site, but there are fewer cracks and both the left and right
banks will be sound if the talus is removed.

A rough comparison study was made for the original and downstream
sites. Based on this study, the development scheme at the upstream
site will be economically advantageous, but a need remains for further
investigations for comparison of the two proposals.

The dam site is located on the Panbyeon River approximately 25 km upstream from the conjunction with the Nagdong River mainstream and about 15 km east of Andong City.

The river gradient in this vicinity is gentle at about 1/570, and the river flows northwest meandering widely until it merges to the Nagdong River.

The dam site has a stable topography at both left and right banks where outcrops of gneiss are seen, while there are almost no deposits of sand and gravel at the river bed so that it is a favorable condition for a dam.

The right bank immediately upstream of the dam site is gullied and thin ridges exist at 3 places, but there is exposed rock along gully surfaces so that special problems are not posed.

It is thought materials for the dam can be obtained upstream of the dam.

Since it is presumed there will be a fairly large number of objects requiring compensation in the reservoir area, detailed investigations should be made and further examinations carried out with regard to the height of the dam.

A - 89

The project site is at the upstream part of the Nakdong River mainstream and is located approximately 60 km west of Andong City.

This site is immediately below Pung Ji Bridge approximately 5 km downstream from the site originally proposed and is considered to be superior to the original site as the water storage efficiency of the dam would be far better, and therefore, selected as an alternative site in this present study.

There is a site which had been investigated many years ago about 5 km downstream from this one, but there is a portion of low elevation at the left bank which would require construction of a long subdam and so no economic comparison can be made.

Although the high water level of the dam will be restricted by the elevation of Andong City, it was tentatively planned at 87.7 m. The river gradient in the vicinity of the dam site is gentle at around 1/2,000, and there are wide distributions of thickly deposited sand and gravel layers both upstream and downstream reaches of the dam, and the river meanders in large sweeps.

The basal rock is granitic gneiss, and while the right bank has outcrops and is sound, the left bank shows considerable weathering of schistous gneiss.

Meanwhile, with respect to the geology of the originally proposed site, although the existence of fault cannot be confirmed, since there are dislocations of ground strata, it is possible for small scale fault to exist at the river bed.

It is thought necessary for further geological survey for dam site and topographical survey for the reservoir, and detailed investigations for compensation necessary for study of the dam height.

16-51 Hamyang
The projected Hamyang site is at the upstream part of the Nam River located approximately 190 km above the point where the Nam River merges to the Nakdong River mainstream.

Since the river gradient at the originally proposed dam site is approximately 1/60 and very steep so that efficiency of water storage would be poor and total storage capacity small, a scheme was formulated where a dam would be provided at the Sininweal site about 6.5 km upstream from the original site and head would be utilized by a tunnel through the leftbank.

The sininweal site is stable topographically compared with the originally proposed dam site. Both banks consist of diorite (black) and there are outcrops at the river bed and deposits are thin so that the geology is suitable for a dam foundation.

On the other hand, faults are developed at the downstream side of the original site, and accordingly, there are small scale faults cutting across the river.

There is a large number of objects requiring compensation in the area scheduled for reservoir and it will be necessary for further topographical surveys and investigations to be carried out regarding property compensation. Compensation costs have been estimated and listed up in this study referring to figures at other sites.

The project site is located at a point on the Dog River approxi-
mately 43 km upstream from this river's conjunction with the Nam River.
The river gradient in the vicinity is about 1/120 and there is wide
meandering at the downstream part.

The center of the dam previously selected is lined on a collapsed
slope and is underirable as a location of dam. Consequently, an
examination was made shifting the dam axis approcimately 200 m upstream
from the originally proposed site.

Although a weathered layer 2 to 3 m thick can be seen at the surface
of the left bank of the new site, the slope itself is stable. There is a
weir at the river bed and the thickness of sand and gravel layer is
estimated at 2 to 3 m.

The right bank side is covered with 1 to 2 m of talus, but there
are occasional outcrops of fresh gneiss and there will be no special
problem in dam construction.

The project in this case was formulated as a power generation
scheme involving a tunnel shortcutting meanders of the river.

Since there is a very large number of objects requiring compen-
sation within the area scheduled for reservoir, it will be necessary
for further detailed investigations of compensation objects upon
preparation of topographical maps.

DATE   FIG.

A - 103

The project site is located at the upper reaches of the Geum River, approximately 180 km upstream from Daecheong Dam now under construction.

The river gradient in the vicinity is relatively gentle, about 1/500. The project sites of Sutong and Myeongcheon are located downstream of this site and each will be developed as a dam-type scheme.

For the Yongdam Development Project, there is an upstream alternative site approximately 6 km upstream of the original one straddling National Highway No. 19 which runs from Daejeon through Yongdong to Namweon, where investigations including boring have been made in the past.

The right bank at the original dam site is steep with a slope of about 40°, while the left bank is slightly more gentle. The river-bed width is around 200 m and there is a deposit of sand and gravel albeit thin. The geology consists of granitic gneiss and the top soil is not thick.

Regarding the upstream site, there are wide terrace and talus deposits at the right-bank from the end of which is a cliff of about 70°, above which there is a flat terrain. Weathering at this part is severe and is thought to be about 40 m in depth.

Outcrops are seen at the left bank, the slope of which is about 50°, and talus on the top of the slope is scarce. Judging from the results of past boring thickness of the gravel layer at the river bed is thought to be 2 to 3 m.

Geologically, the problems will be whether the saddle at the right bank and the weathered rock underlying the talus will be adequate for the dam foundation.

Topographically, there is a possibility that a tectonic line runs north-south at the river bed or the bottom portion of the terrace. (The existence of a brecciated zone has been confirmed in past boring investigations.)

Based on geological comparisons, although the condition of the tectonic line is not clear, the downstream original site is more stable.

Songpung Village (ginseng production area) will be submerged in the case of the original plan to increase compensation costs. Detailed investigations regarding property compensation along with topographical surveys inside the reservoir area are required.

The project site is situated on the Geum River mainstream approx-
imately 33 km downstream from the Yongdam Dam site, the river flowing
from the Yongdam site in the northeast direction while meandering
widely.   The gradient of the river is gentle at aroung 1/500.

The dam site is located approximately 1 km upstream from Sutong
village.   Both left and right banks form cliffs of 35° to 70°.   The left
bank is a steep cliff from the river bed up to about 60 m, above which is
a gentle ridge.   The right bank has rhyolite exposed over its entire
surface and there are no deposites.

According to "Report on Basic Survey of Sutong Site, 1962, Con-
struction Authority of Korea" prepared by the Korean Government in 1962,
the deposits at the river bed are around 2 m in thickness with dikes of
quartz porphyry at the river bed, and investigations for existence of
fractured zones will be required.

Muju town is located at the end of the reservoir and it will be
necessary for further detailed topographical surveys and compensation
studies to be carried out.

The project site is located on the Geum River mainstream approximately 43 km downstream from the Sutong site and approximately 4 km upstream from the Yanggan village on the National Highway No. 4.

The river gradient is gentle at around 1/500.

The left and right banks at the dam site are sloped at 30° to 40°. Outcrops of granite continuing along the entire surface on the right-bank can be seen on the road along the river. At the left bank the granite changes to dikes of quartz porphyry. However, neither of the banks poses a problem as a dam foundation.

Bedrocks with cracks 1 to 3 m in depth are found upstream and downstream of the dam center at the right bank. The width of the river bed is approximately 140 m, the entire surface being covered by gravel with no outcrops to be seen.
There are many distributions of sand and gravel layers along the river both upstream and downstream from the dam site but it appears that sand is comparatively abundant with little gravel content.

Paddy fields of the Yansang village exist in the area to be submerged in the reservoir and it is thought necessary for detailed investigations of property compensation to be carried out hereafter similarly as for other sites.

The project site is located on the Song River, a tributary of the Geum River, approximately 13 km upstream from the confluence of the two rivers and about 4 km along a local road branching north from National Highway No. 4.   An irrigation weir of height about 1 m is situated at the dam site.

The river gradient in this vicinity is approximately 1/850.   The river flows west from about 10 km upstream of the dam site meandering widely to north and south.

The left bank at the dam site is a steep slope of around 40° to 50°, while the right bank is a slope of about 30°.
The bed rock consists of schist at both banks, and although it is thought there will be no problem as a dam foundation, immediately up-stream of the right abutment a thin topsoil and cracking of bedrock can be seen so that it would be advisable to shift the dam axis downstream about 10 m.

The Seoul-Pusan Highway runs in the area proposed for the reservoir, and there are many other objects requiring compensation, then this site may not be considered advantageous from the standpoint of economics.

The project site is located at the upstream part of the Seumjin River approximately 111 km upstream from the mouth of the river. The existing Seumjingang Dam is located approximately 27 km further upstream.

The river gradient in the vicinity of the dam site is gentle at around 1/800, and the development scheme will be one of dam type.

The Jeokseong Dam site has a remaining catchment area of 241 km^2 because of water diversion from the upstream Seumjingang Dam, and annual inflow will be small.

There are two places of low elevation at the top of a gully approximately 400 m upstream of the dam site. The geology of this vicinity is considerably weathered into decomposed granite. The depth of weathering is thought to be more than 5 m.

The geology of the dam site is comprised of granite with outcrops at both left and right banks and at the river bed, and although there is no problem as a dam foundation, there is a cover of about 5 m of talus at the right bank. It is thought that the cover will become thinner if the dam axis were to be moved 30 to 50 m upstream.

The project site is located at the lower reaches of the Boseong River, a tributary of the Seomjin, and is about 25 km upstream from the junction of the two rivers. The river gradient in the vicinity of the site is gentle at approximately 1/1,200.

The objects of investigation in this study were the Juam site and the No. 2 Boseonggang Dam site as an alternative. Both are being considered for dam construction to secure agricultural and industrial water which would be required in connection with the reclamation project on the southwest coast presently being contemplated.

There is also a proposal for water diversion to the south coast from this site, but there is No. 1 Boseonggang Dam existing about 70 km upstream from this project site from where almost all inflow from 275 km^2 catchment area is being diverted.

In this study, the dam scales were examined for the Juam and No. 2 Boseonggang sites without considering water diversions. For Juam Dam, the vicinity of the site in the original proposal is suitable, but since the left bank consists of a thin ridge and talus deposits are estimated to be thick, it will be advisable for the dam axis to be shifted about 50 m downstream from the site ogiginally selected.

The left bank at the downstream side has granite exposed up to mid-height and there is little overburden. Small-scale faults are expected to exist at parts of low elevation and it is thought necessary for these to be clarified through further investigations. The coverage is thin at the right bank and outcrops are also seen so that there will be no problem.

There is a large number of objects requiring compensation in the area scheduled for reservoir and it will be necessary for further detailed investigations to be made regarding property compensation.

24-A4 No. 2 Boseonggang

This site was planned as an alternative of the Juam site. The site originally selected is severely weathered at the left bank along the national highway, with deeply weathered portions (decomposed granite) running along the river. Further, there are faults running underneath and at the river bed, then the site is unsuitable for a dam site.

An alternative site was selected upstream of this site. This alternative site is located approximately 10 km downstream from No. 1 Boseonggang Dam, with its geology comprised of gneiss. The geology of the left-bank is good and there is no fear of faulting at the river bed. The bedrock at the righ-bank is slightly loosened at places, but there is no problem as a dam foundation.
