5-3-4 Laboratory Test

The results of the laboratory test are shown in Table 2-14. The mean values of resistivity and chargeability for each rock are as follows.

Rock	Resistivity (ohm-m)	Chargeability (ms)
Quartz vein	16,919	25.9
Claystone・Siltstone	646	3.9
Shale	1,389	9.8
Sandstone	2,602	13.6
Phyllite	1,726	12.1
Schists	1,716	12.1
Granite	1,734	13.5

The laboratory test offered the result matched to the CSAMT data that the resistivity of the rock samples are higher than 1,000 ohm-m except claystone and siltstone. Especially, the resistivity of the quartz vein is a figure higher (more than 10,000 ohm-m) than that of the other rocks. However, the resistivity of the quartz vein varies widely, depending on the condition of fissures. The samples containing few fissures measured higher than 10,000 ohm-m, while the samples containing remarkable fissures measured a figure lower (about 2,000 ohm-m). The sandstone and schists of the host rock had high resistivity of about 2,000 ohm-m. The granite had the same value as the host rock. However, the samples of the granite were weathered and cataclastic. Thus, the resistivity of the fresh rock in the deep zone will be still higher. Claystone and siltstone were the lowest (about 600 ohm-m) of the rocks in the survey areas. A low resistivity of 600 ohm-m existed in the shale also.

The chargeability of the samples measured about 10 ms except the quartz vein. The mean value of the quartz vein is 25.9 ms. However, the chargeability of the quartz vein varies widely, depending on the existence of pyrite. The samples containing no pyrite measured several ms, while the samples containing pyrite measured the largest of 96 ms. Relatively large chargeability of about 20 ms existed in phyllite and schists. The graphite schist measured small (5.6 ms) in chargeability. This small chargeability is due to the sample containing few amounts of graphite. The laboratory test gave the obvious contrast between the quartz vein containing pyrite and the other rocks in the survey areas.

Table 2-15 Results of Laboratory Test

No.	Rock	Resistivity ohm-m	Chargeability ms	Remarks
1	Quartz vein	2,962	2.0	limonite diss., porous
2	Quartz vein	1,617	96.0	Py diss., porous
3	Quartz vine	27,539	5.4	limonite diss., porous
4	Quartzite	35,558	0.1	
	Average Value	16,919	25.9	
5	Claystone	689	2.9	
6	Claystone	782	5.0	
7	Siltstone	524	3.8	
8	Siltstone	590	3.9	
	Average Value	646	3.9	
9	Shale	627	23.4	
10	Shale	1,313	4.1	
11	Shale	2,228	2.0	
	Average Value	1,389	9.8	
12	Sandstone	2,685	10.2	sericit
13	Sandstone	905	6.5	
14	Sandstone	2,917	12.3	
15	Sandstone	3,567	19.6	reddish brown
16	Sandstone	2,934	19.3	reddish brown
	Average Value	2,602	13.6	
17	Phyllite	2,220	20.4	
18	Phyllite	1,012	4.0	
19	Phyllite	1,947	12.0	
	Average Value	1,726	12.1	
20	Schist	871	11.5	
21	Sericite schist	1,371	3.7	
22	Sericite schist	1,238	3.1	
23	Graphite schist	3,385	5.6	
	Average Value	1,716	6.0	
24	Granite	1,833	12.9	weathered, cataclastic
25	Granite	1,635	14.0	weathered, cataclastic
	Average Value	1,734	13.5	

5-4 Discussion

(1) Resistivity Features

The laboratory test results and geologic information led to the following resistivity features about the rocks and geologic structure in the survey areas.

1) High Resistivity

In the survey areas, the group of quartz veins and the granite are assumed to form higher resistivity than the host rock.

The quartz vein containing few fissures is extremely high (more than 10,000 ohm-m) in resistivity. However, it is very difficult to extract narrow high resistivity zone in width by this measurement system. In the case of the zone where many quartz veins are concentrated (the group of quartz veins), it is sufficiently possible to extract a high resistivity zone related to quartz veins. MT method is not much sensitive to high resistivity. Thus, the width of the group of quartz veins is expected to be more than 100 m if a high resistivity zone related to quartz veins is extracted by this measurement system. When fractures develop in the group of quartz veins, it is possible that the resistivity of the group is lowered and a high resistivity zone related to quartz veins is not extracted.

When the samples of granite were weathered and cataclastic, they had the same resistivity (1,734 ohm-m) as the host rock. When the granite is fresh in deep zone, it seems that granite is several times higher in resistivity and a high resistivity area related to granite is extracted.

The laboratory test shows that the existence of the other rocks might not form higher resistivity.

2) Low Resistivity

In the survey areas, claystone and siltstone, fracture zone and the layer containing graphite are assumed to form lower resistivity than the host rock.

The laboratory test showed that claystone, siltstone and one of the shale had the lowest resistivity (about 600 ohm-m). When fractures exist in these rocks, they lower further their resistivity..

In fracture zones, low resistivity zones are generally extracted, because they are high permeable (high conductible) . Many of fracture zones have a figure lower resistivity less than host rock.

Graphite has extremely low resistivity less than several ohm-m. The resistivity of the layer containing graphite is lowered depending on its content.

(2) Relations to Geologic Structure

The figure arranged the resistivity structure sections (2-D analysis) in the sequence of the lines is shown in Fig. 2-63 to grasp three dimensional resistivity structure. The followings are the geological interpretation to resistivity structure on the basis of the above resistivity features.

1) Da Mai Area

Resistivity structure :The high resistivity areas are distributed broadly below about 300 m from the surface. The high resistivity zones towards the surface were detected and at the Nos. 7 and 8 on lines D-3 to D-5, and in the southern part of lines D-7 to D-9.

Interpretation: The high resistivity areas in the deep zone seem to be reflected by the distribution of granite. The high resistivity zones seem to result from the group of quartz veins or the stock of granite. They are expected to be relatively steep and extend to the deep zone.

2) Gang Area

Resistivity structure :It is layered structure - NW-SE strike with 20 to 30 degree S dip. The high resistivity layer is distributed in the shallow zone and the low resistivity layer is distributed in the deep zone. In the shallow zone, the high resistivity zones more than 5,000 ohm-m were detected in the southern part of lines G-5 to G-7, the middle part of lines G-3 to G-4, and the northern part of lines G-4 to G-7. These high resistivity zones do not extend to the deeper zone.

Interpretation: The strike and dip of the resistivity structure matches with those of the geologic structure. The high resistivity zones in the shallow zone seems to result from the group of quartz veins. They will have gentle dip, since they are distributed rather broadly in the shallow zone. The low resistivity layer is considered the layer composed of claystone, siltstone, shale or the layer containing graphite. In the case of the former, fractures will develop in the layer because of the existence of the low resistivity zones less than 50 ohm-m. In the case of the latter, a considerable amount of graphite will be involved.

3) Ngan Me Area

Resistivity structure :The resistivity is lowest of the three areas. The low resistivity areas in the western part will continue from the eastern part of Gang area. The high resistivity zones were detected in the southern part of line N-5 and the middle part of line N-2. The high resistivity zone in the southern part of line N-5 extends to the deeper zone. The vertical zone with low resistivity less than 50 ohm-m was detected from No. 8 on line N-1 to No. 10 on line N-2.

Interpretation: Since the host rocks in this area is relatively low, the high resistivity zone related to quartz veins is assumed to be extracted apparently smaller than in the other areas. The high resistivity zones noted above seems to result from the group of quartz veins. Especially, the zone in the southern part of line N-5 extends to the deeper zone with steep dip and is expected to extend to the east. The low resistivity zone seems to be attributed to fracture zone.

(3) IP Method

The laboratory test results gave the obvious contrast between the quartz vein containing pyrite and the other rocks in the survey areas. When the IP method is applied to this areas, it is graphite that adversely affects the data. The laboratory test showed that the IP effect is small, in the case of containing few amounts of graphite. If a layer contains a considerable amount of graphite, the CSAMT method sensitive to low resistivity should extract a low resistivity area because of the extremely low resistivity (less than several ohm-m) of graphite.

Consequently, it is considered that the high resistivity zones extracted by this survey contain few amounts of graphite and IP response is little affected in these zones. Thus, the IP method is available for these high resistivity zones in order to delineate prospective parts.

Since the CSAMT method is not much sensitive to high resistivity and this measurement was carried out with the potential electrode spacing of 100 m, the resistivity distribution related to the mineralization was not able to determine with sufficient accuracy. From this standpoint also, it is significant to carry out the IP method sensitive to high resistivity with high density.

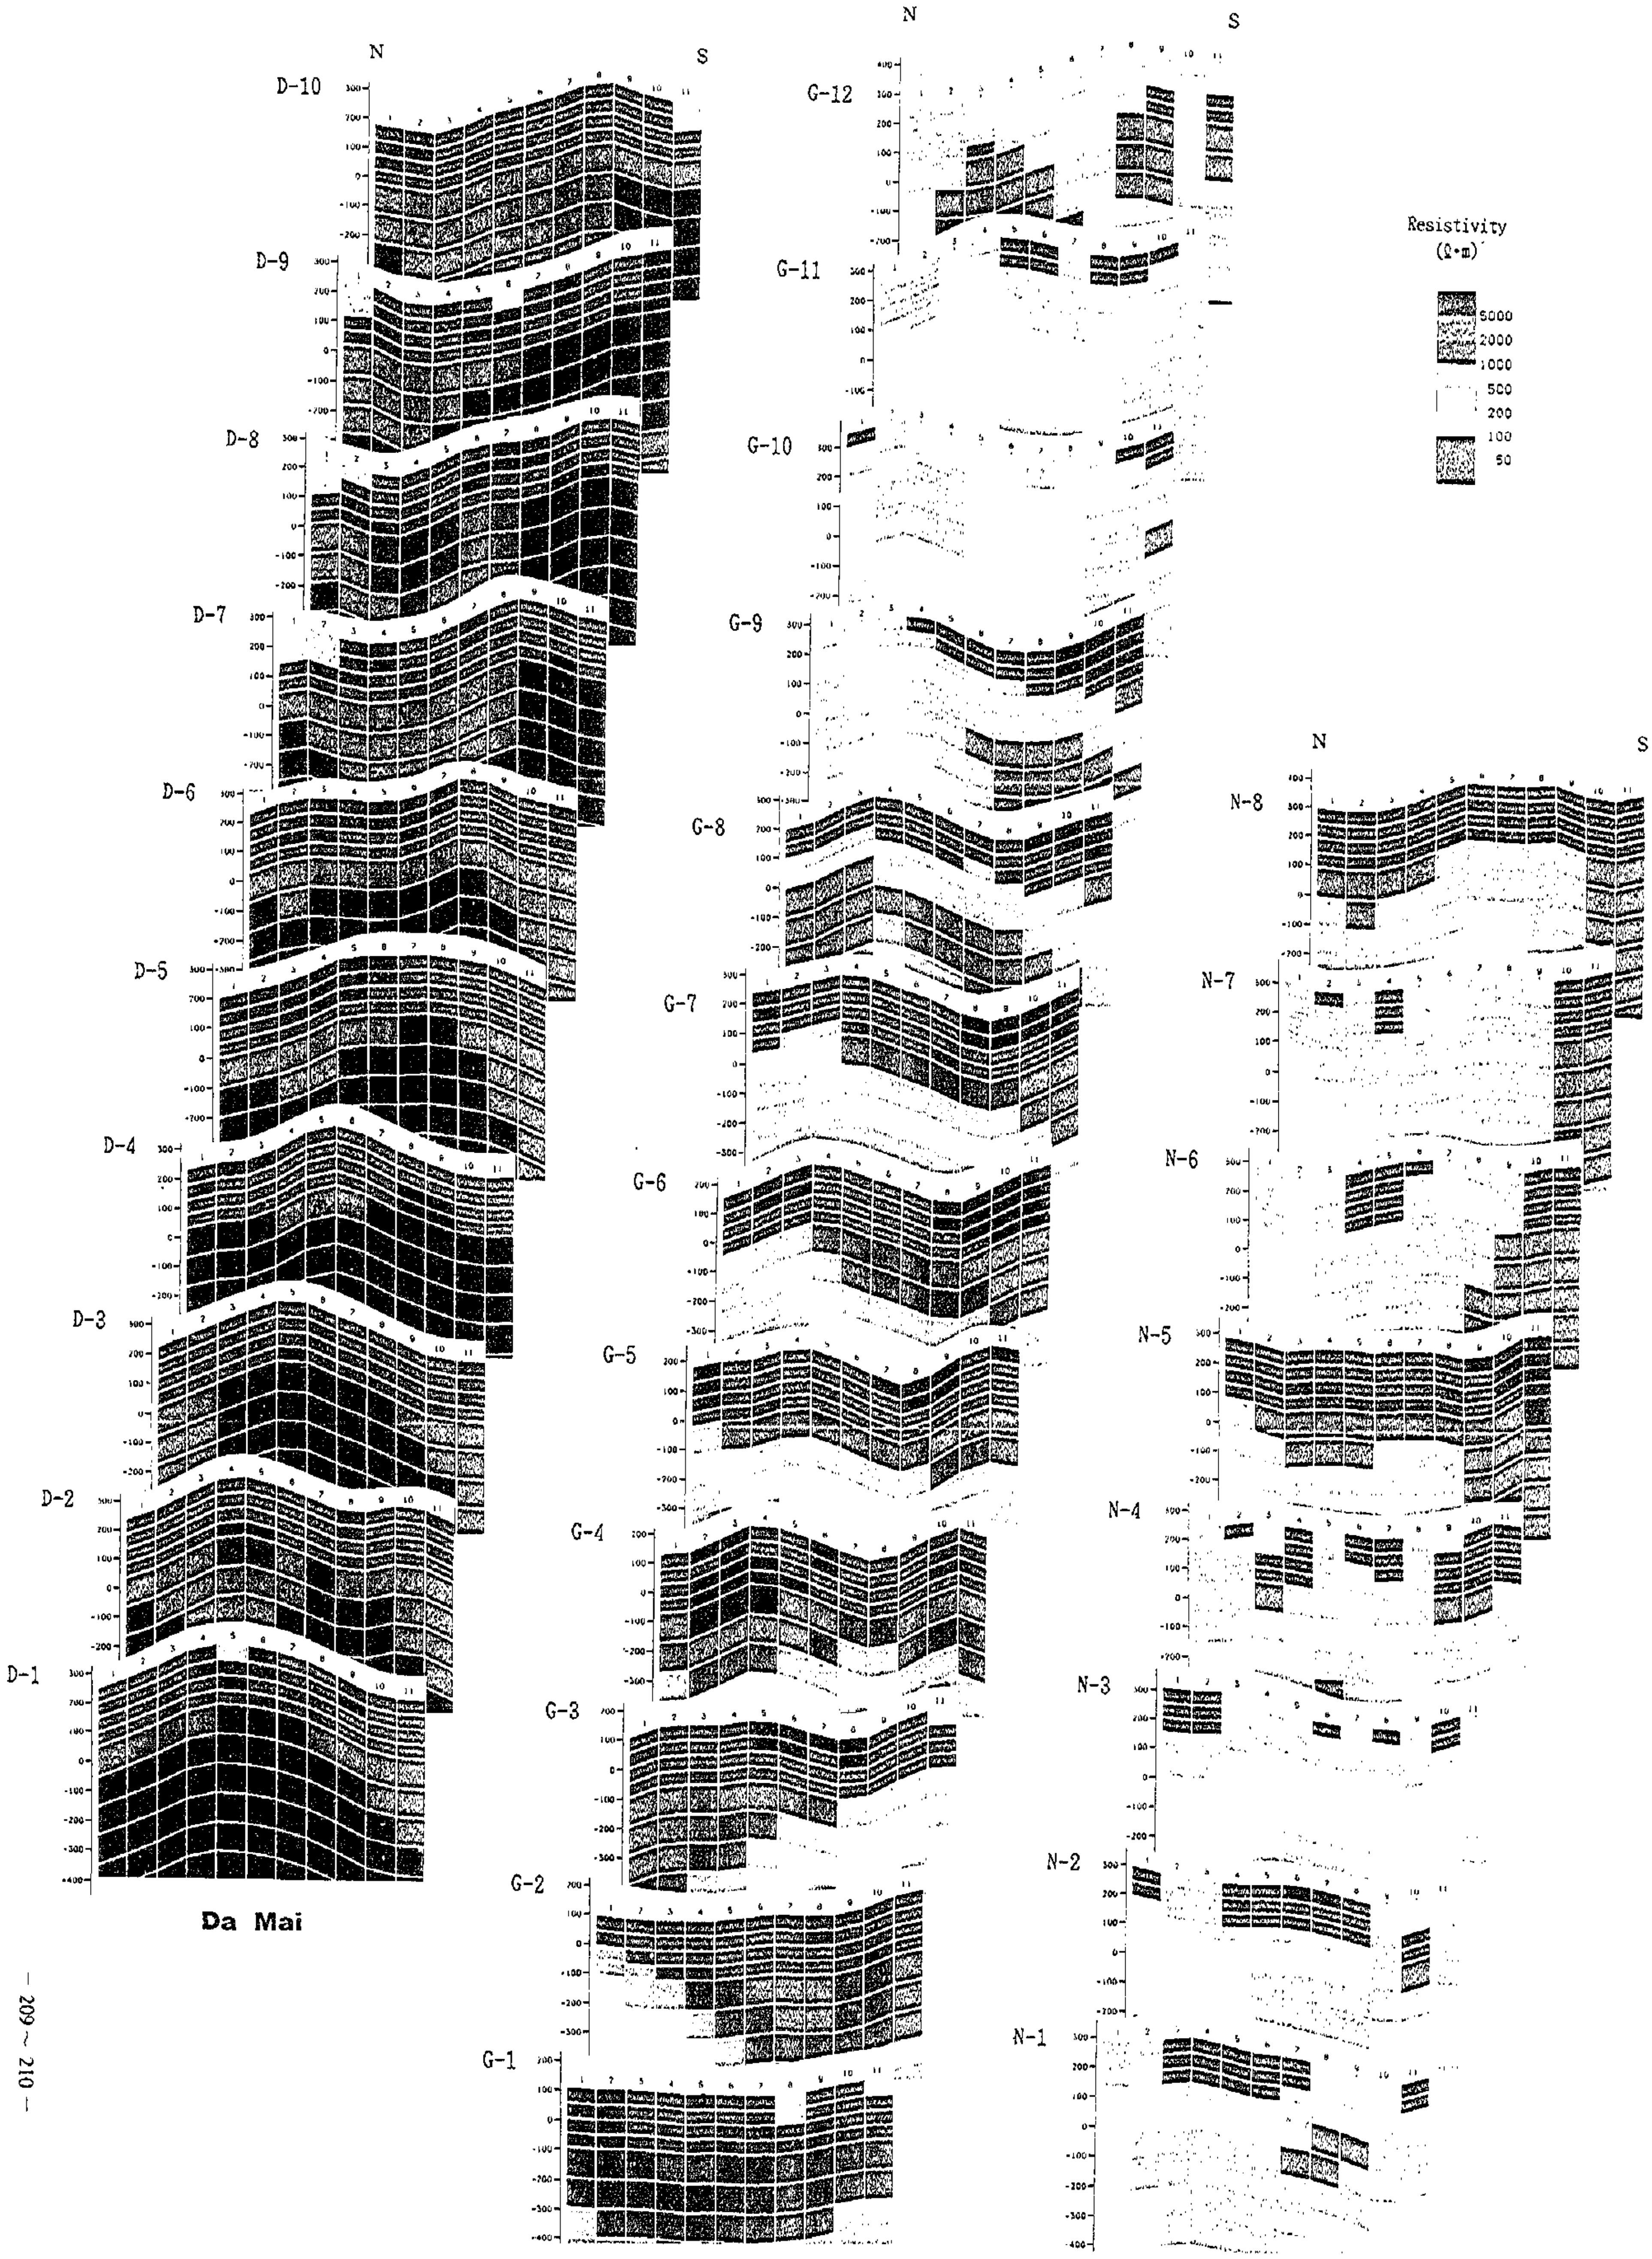

Fig. 2-63 Results of the CSAMT Analysis

PART III CONCLUSIONS AND RECOMMENDATIONS

PART III CONCLUSIONS AND RECOMMENDATIONS

Chapter 1 Conclusions

On the basis of the results of the first phase works comprising regional geological survey, stream sediment geochemical survey, panning survey, detailed geological survey and CSAMT geophysical survey, the following conclusions are obtained.

(1) Regional Geology and Geologic Structure

The distribution of six major stratigraphic units from the Cambrian to the Quaternary systems consisting of 14 formations was surveyed and the geologic map of 1:50,000 scale was prepared in the Bo Cu area by the regional geological survey this phase. Geostructurally, the survey area is characterized by a series of anticlines and synclines called Bac Son anticlinorium whose axes orientate from NE, ENE to WNW. The Bo Cu anticline, whose axis trends WNW-ESE, is defined in the western part of the survey area where gold mineralization is extensively developed. Three major fault systems were distinguished in the survey area: NW, N-S, and NE systems. The main orogenic activity which resulted in the regional folding and tectonic faults in the Bo Cu area is interpreted to be occurred in the Triassic or later period. Small stocks of granite were found at the northern part of the survey area. The nature of this granite is discussed based on the whole rock analysis. It is concluded that this granite belongs to the granitoids of the magnetite series and of the S-type intruded at the marginal zone of the South China plate.

(2) Galena Mineralization

Regarding metallic mineral deposits in the Bo Cu area, two significant mineralizations, gold-bearing quartz veins and galena veins, were recognized. The galena veins occur mostly in the Carboniferous-Permian limestone. Several galena showings were found in the course of the regional geological survey and geochemical exploration. Some of them contain a significant amount of lead and silver. The similarity of geology and mineralization is discussed with the galena deposit in the Cho Dien area which is a famous Pb-Zn district in the northern Vietnam. The potential of galena resources in the Bo Cu area is estimated to be small from the survey results. As for the other mineral resources, a sedimentary phosphorite seam and a couple of magnetite lenses, both are considered to be small for that type of deposit, are known within the survey area.

(3) Gold Mineralization

Gold-bearing quartz veins occur extensively in the western part of the Bo Cu area. Although the width of each vein is not magnificent, they sometimes occur together forming a vein zone of 100-300 m wide and 500-1,000 m long. The system of quartz veins and the nature of gold mineralization were investigated by the detailed geological survey. On the basis of the results of studies such as geologic environment, ore and gangue mineralogy, alteration, chemical analysis and fluid inclusion, it is interpreted that the type of mineralization is mesothermal gold vein hosted by sedimentary and metamorphic rocks of the Cambrian Mo Dong and Than Sa Formations. Two vein systems were distinguished by means of the stereo net analysis. One is N80°E with steeply dipping S, and another is E-W with gently dipping S. The veins occur on the wing of the Bo Cu anticline, and it is interpreted that the formation of veins is controlled structurally by the regional folding activity started probably from the Triassic period. According to the detailed geological survey together with the results of geochemical exploration, three areas for gold-bearing quartz veins have been examined, and potential for each area is preliminary evaluated. It is not likely to occur a big scale deposit in this area when seeing from the relative narrow and low grade quartz veins as well as the scale and intensity of geochemical anomalies. Among three areas and their extensions, Da Mai-Khe Dui and Ba Khe are promising prospects for gold resources.

(4) Geophysical Survey

The resistivity of the survey areas are high as a whole. The resistivity structure matches with the geologic structure. Especially, the Da Mai area has higher resistivity than the other areas and the high resistivity areas suggesting the distribution of granite were detected broadly below about 300m from the surface. With reference to the mineralized zone, the high resistivity zones resulting from the group of quartz veins more than 100m in width were extracted. The known prospects related to these zones and their features are as follows:

Da Mai area

- No.7 and 8 on lines D-3 to D-5 (Da Mai, extension to deep zone, steep dip)
- Southern part of lines D-7 to D-9 (Goc Sen, extension to deep zone, steep dip)

Gang Area

- Southern part of lines G-5 to G-7 (Khe Gang, shallow zone, gentle dip)
- Middle part of lines G-3 to G-4 (Khe Gang, shallow zone, gentle dip)
- Northern part of lines G-4 to G-7 (no known prospects in the vicinity, shallow zone, gentle dip)

Ngan Me area

- Southern part of line N-5 (Ba Khe, extension to deep zone and east, steep dip)
- Middle part of lines N-2 (Ba Khe, shallow zone)

The laboratory test results gave the obvious contrast between the quartz vein containing pyrite and the other rocks in the survey areas. IP method is available for the high resistivity zones extracted by this survey in order to delineate prospective parts, because these zones seem to contain few amounts of graphite.

(5) Da Mai-Khe Dui Prospect

The distribution of gold mineralization in the Da Mai-Khe Dui prospect is approximately 200-300 m wide and more than 1 km long. Gold-bearing quartz veins in the Da Mai-Khe Dui prospect are characterized by the vein trend of steeply dipping S. A significant amount of sulfide minerals is contained in the vein. Assay results by the GSV survey were significant this prospect. The mining activity by local people there is already at the waning stage. High grade ores near the surface were nearly mined out. However it still has significant gold resources in the deeper part and the extensions. The gold mineralization is expected to extend to the east through the Northeast of N. Bo Cu until Khe Ma gold anomalous zones for approximately 5 km. Remarkable Au anomalies of stream sediments and some gold anomalies of pan concentrates were found in the Northeast of N. Bo Cu and Khe Ma this phase.

(6) Ba Khe Prospect

The Ba Khe prospect in the Ngan Me area is understood to be another target for the further exploration. Adits and inclined shafts are distributed for about 900 m along the creek. Two systems of veins, E-W with steeply dipping S and E-W with gently dipping S, occur together in this prospect. The width of veins changes variously; some part shows a lens-like shape. Branching and joining of veins are frequently observed. Although assay results of ore samples were rather disappointing this time, the visible gold occasionally occurs in some part of quartz veins. The activities of local miners are limited above the ground water level. The gold mineralization is likely to extend both westwards to the West Ba Khe creek and eastwards to the Bai Vang gold anomalous zone for approximately 3.5 km. In Bai Vang, a couple of significant Au anomalies in stream sediments and tens of gold anomalies of pan concentrates were detected this phase.

(7) Other Prospects

The Cay Thi and its surrounding zone in the Gang area also have some potential for gold resources. Two zones of veins both are gently dipping S occur in this prospect. These two zones run parallel each other at 40 m apart vertically. Several significant assay results were obtained this phase. The other interesting gold prospects in the Gang area are Khe Gang and Khe Hoac. Gold-bearing quartz veins in these prospects show similar trend and nature as in the Cay Thi prospect.

Chapter 2 Recommendations for the Second Phase Survey

Da Mai-Khe Dui Prospect

It is recommended that the detailed survey comprising IP survey and geological survey (including trenching and geochemical rock-chip survey) shall be made in this prospect and its eastern extension for the purpose of defining the drill target. After the detailed survey, a reconnaissance drilling for testing the IP anomalies shall be made.

Ba Khe Prospect

A detailed survey comprising IP survey and geological survey (including trenching and geochemical rock-chip survey) is recommended in the Ba Khe prospect and its extensions in the next phase. The purpose of this survey is to define the drill target for the further exploration.
