As for Olt County, there is a little augmenting trend of the vegetation stress in the northern forest area in the Study Area. As for the forest located in the northwestern Slatina and northeastern Caracal, the stress increased slightly from 1990 to 1997.

These spectral changes of vegetation can be seen on each false-color image.

The results from the analysis using LANDSAT/TM data were put to practical use to select vegetation survey areas and forest survey plots, and also used as some materials for the decision of soil survey area at the third field survey. The survey area selected by detecting areas with remarkable temporal change in the vegetation stress and by reviewing the information of the deteriorated forest distribution obtained from counterpart personnel.

In the third field survey, the relationship between the vegetation stress change and the extent of forest deterioration was confirmed by the Study Team. There was some distinguished vegetation stresses in the deteriorated forests. However, the correlation between the stresses and forest condition was not clear in areas with low stress. LANDSAT/TM was found to be useful, and the image analysis was effective when the Study Area is larger, as in the Study, to grasp overall distribution and condition of forests.

2.4.3 Forest Composition

(1) Forest Stand Composition and Forest Decline Fact-Finding

A belt-transect survey to classify forests into forest vegetation types was conducted at 32 survey plots in 19 forests shown in App. D-1 and App. D-2. App. D-3 shows the results of the belt transect survey for 11 forest vegetation types. At the same time, a forest decline fact-finding survey was conducted at the 22 plots shown in App.D-1 and App. D-6. A forest decline fact-finding survey was also conducted at the belt-transect survey plots using belt-transect survey stands.

1) Stand Composition of Natural Forests

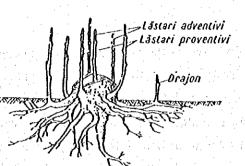

Types of Natural Regeneration

Of the 32 survey plots where the belt-transect survey was conducted to classify forest vegetation types, 30 plots are natural forests with the exception of plantations of *Populus* spp. and *Robinia pseudoucacia*. These forests have been

formed by natural regeneration and *Quercus* spp. is the main species. However, they can be classified as stands regenerated by seedlings and stands regenerated by coppicing. The former are the result of natural regeneration by seeding while the latter are further classified as those regenerated by coppice shoots and those regenerated by root suckers.

In Romania, coppicing is classified as coppice shoot (*Lastar*) and root sucker (*Drajon*) based on the section of coppicing and the types of coppicing for each *Quercus* species is identified as shown below.

Types of Coppicing

(by E.G. Negulescu)

Types of Coppicing by Quercus Species

Species	Lastar	Drajon
Q. cerris	0	ΔX
Q. frainetto	0	О
Q. petraea	0	Х
Q. robur	0	X
Q. pedunculiflora	0	X
Q. pubescens	О	Δ

Legend

O: abundant

△ : few

X : none

(Flora forestiera lemnoasa a romaniel, Victa Stanescu)

The relationship between the types of coppicing and forest decline is shown in Table 2-4-6. The survey sheets reveal that the degree of decline with root sucker is less than that with coppice shoots at Perisor UP III 57A and Craiova UP I 81B. However, no clear relationship between the difference in coppicing type and forest decline is established not only for *Q. frainetto* but also for *Q. cerris* and *Q. pubescens* at Vulturesti UP III 43D and Slatina UP V 32C.

Nevertheless, damage due to decaying bacilli was often found at trees regenerated by coppice shoot. In terms of species, the degree of decline of trees regenerated by coppice shoot is higher for *Q. frainetto* than *Q. cerris*. In short, it is judged that the general relationship between coppicing and forest decline is that trees regenerated by coppice shoot are more prone to decline that trees regenerated by root sucker.

The distinction between trees regenerated by root sucker and trees regenerated by natural seeding can be established for saplings but is difficult for mature trees. Table 2-4-7 shows the survey results for regenerated *Q. frainetto* saplings. According to this survey, the actual position of root sucker is within a 1.8 m radius of the mother tree.

② Formation of Natural Forests

Close observation of the 30 stands reveals that some have been created by seeding, some have been established by coppicing and some show a mixture of these two types of regeneration. The No. 13 belt-transect survey plot at Tarnava is an example of a mixed stand of Q. cerris and Q. frainetto regenerated by coppicing [Fig. 2-4-3-(1) and Table 2-4-8-(1)] while the No. 26 belt-transect survey plot at Vladila is an example of a Q. pedunculiflora stand regenerated by coppicing [Fig. 2-4-3-(2) and Table 2-4-8-(2)]. Broad-leaved species which are mixed with Quercus spp. are mainly Fraxinus excelsior, F. ornus, Acer campestre, A. negundo, Ulmus minor, U. laevis, Tilla platyphyleos, T. argentea, Pyrus pyraster and Crataegus monogyna. The results of the belt-transect survey suggest that the height of the trees observed at these plots ranges from 15 m to 35 m with a maximum dbh of 116 cm and a density per ha of 160 - 1,360 trees.

The number of regenerated seedlings by natural seeding found in the belt-transect survey plots is shown in App.D-4. At least 100,000 seedlings per ha at the initial stage of regeneration are required to expect the successful growth of a stand by means of regeneration by natural seeding with 30,000 - 40,000 seedlings per ha surviving after five years (Morio Imada, Study on Method to Produce Structural Timber from Quercus mongolica var. grosseserrata, 1972). Quercus spp. which produce the highest number of seedlings in the survey plots are Q. cerris and Q. petraea. The number of seedlings of Q. frainetto and Q. robur is a maximum of 10,000 - 20,000 per ha. Among broad-leaved trees other than Quercus spp., Fraxinus excelsior produces the highest number of seedlings, followed by Acer campestre and Tilia argentea.

③ Growth of Root System

A root system survey was conducted at a declined forest at Craiova UP I 81B and Craiova UP IV 142C (Table 2-4-9) to obtain information on the state of root system growth with a view to conducting drainage and infiltration work.

Table 2-4-9 Root Distribution

Forest	Species	No.	Tree	DBH	Degree		Lateral root	S	Тар	roots	Vital
name		1	height	1	of	Number	Thickness	Depth of	Depth	Thickness	activity of
	* · ·	:		140	dectine			distribution		of 1m Depth	fine roots
			(m)	(cm)		(lmxlm)	(cm)	(cm)	(m)	(cm)	*
Cosoveni	Q.frainetto	1	12	15	2~3	36	10.8	10~60	more than 2m	50	Low
		2	12	18	2~3	23	10.4	10~60	more than 1.5 m	20	Low
Criva	Q.frainetto		12	18	2~3	24	33.7	10~60	more than Im	19	Low
		2	11	20	1 1	29	33.4	10~60	more than Im	24	Moderate
		3	10	16	2~3	22	25.9	10~60	more than Im	35 :	Low ·
ICAS	Q.robur	1	25	26	0	35	. 15.5	10~60	more than 1.5m	-	High
							. 1				

The root system of the declined forest of Q. frainetto (tree height of 10 - 12 m; dbh of 16 - 20 cm) has a thick main root at deeper than 1.5 - 2 m. The lateral root density is 22 - 36 roots per m^2 of the soil profile and many are found at a depth of 10 - 60 cm. The surveyed tree of with a decline grade of 3 has less fine roots that the surveyed tree with a decline grade of 1, indicating a lower level of vigorousity.

Comparison between the state of root growth of the surveyed trees and that of a healthy *Q. robur* stand at the ICAS experimental forest found that the vigorousity of fine roots at the ICAS experimental forest was higher than that of the surveyed trees of declined forests, suggesting that the vigorousity of fine roots is affected by the degree of decline of standing trees.

The soil hardness at the root system survey sites is shown in Table 2-4-10. The hardness index measured by *Yamanaka's Soil Hardness Tester* at Criva and Cosoveni shows a high value of 26 - 28 mm below 30 cm of the soil profile. At these sites, the tight clayey soil maintained the moisture absorbed by the soil during the dry weather spell in the second half of the 1980's with the trees surviving this drought but that such moisture was spent at the time of the extremely abnormal dry weather in the early 1990's, making it impossible for the trees to survive.

When drainage and infiltration work is conducted, its distance of 1 - 1.5 m from a tree with a depth of 20 - 25 cm is believed to cause little damage to the root system.

Table 2-4-10 Soil Hardness on the Plots of Root Systems Survey

Forest name	Species	Soil hardness of each soil depth (mm)								
		10 cm	30 cm	50 cm	80 cm					
Cosoveni	Q.frainetto	23	28	27	28					
Criva	Q.frainetto	13	26	26	27					
ICAS	Q.robur	21	Tariff Park (A	25	25					

Note: Measured by Yamanaka's Soil Hardness Tester

Hardness index	Root growth
(mm)	
Less than 23	Easily
23~26	Possible
27~30	Difficult
31~40	Impossible

2) Composition of Artificial Stands

Quercus spp., the main species observed in Dolj and Olt Counties, mainly forms naturally regenerated stands. In the case of artificial stands created by artificial seeding or the planting of seedlings, many stands are noticeably young. Among these artificial stands, the survey was conducted on a planted Q. robur stand and directly seeded Q. frainetto stand.

Fig. 2-4-3-(3) and Table 2-4-8-(3) show the survey results for a 45 year old artificial stands mainly consisting of Q. robur. Of the accompanying species observed, Q. frainetto was regenerated by coppicing from the roots and Q. petraea was planted. The tree density of this stand is 1,180 trees per ha and the crown density is 85%. The average decline grade of the main species, i.e. Q. robur, is 1.7 although 35% of Q. robur show a decline grade of 2.0 - 4.0, illustrating the need for forest restoration. The tree height of the surveyed trees ranges from 6 m to 17 m and the relation between the tree height class and decline grade shows that most Q. robur and Q. frainetto trees in the lower story (6 m - 11 m class) show a high decline grade of 2.0 - 4.0. In contrast, the proportion of trees showing a high decline grade of 2.0 - 4.0 of 28.6% is not that high in the upper story (12 m - 17 m class).

Fig. 2-4-3-(4) and Table 2-4-8-(4) show data for a directly seeded 33 year old Q. frainetto stand. The number of trees per ha is 1,680 with a crown density of 72%.

The average decline grade of this stand is 1.7 with 29.3% of the trees showing a decline grade of 2.0 - 4.0. There is a strong correlation between the tree height class and decline grade as all of the trees in the lower story (5 - 6 m class) fall in the high decline grade range of 2.0 - 4.0. In the upper story (7 - 10 m class), many trees of low tree height class show a high decline grade. (Note: Sec 2-4-3 (1) 4) for a desription of average decline grade).

3) Non-Quercus spp. Artificial stands

Robinia pseudoacacia and Populus spp.

The main non-Quercus spp. artificial stands in Olt and Dolj Counties are huge artificial stands of Robinia pseudoacacia and Populus spp. R. pseudoacacia is imported from North America while Populus euroamericana, a mixed species between European and American species, is common in the case of Populus spp. stands. I-214 which is used as a breeding species is a clone which was developed in Italy and is a recommended species because of its excellent growth.

The No. 15 belt-transect survey plot is an example of R. pseudoacacia at Madona under the jurisdiction of the former Apele Vii Forest Range Office and has been established through regeneration by coppicing from planted R. pseudoacacia [Fig. 2-4-3-(5) and Table 2-4-8-(5)]. The original interval for the planted seedlings was 4 m between rows and 2 m between seedlings and the present tree height is in the 12 - 15 m class. Similarly, the No. 14 belt-transect survey plot is another example of R. pseudoacacia at Celaru, again in an area under the jurisdiction of the former Apele Vii Forest Range Office [Fig. 2-4-3-(6) and Table 2-4-8-(6)] and the height of the upper story trees of this stand is as high as 15 m - 20 m. These R. pseudoacacia stands are inland dune forests located far from the Danube River and, therefore, the water environment is believed to be poor. The grade of die back of these stands of 2.9 for the No. 15 survey plot and 3.0 for the No. 14 survey plot is high. Compared to these R. pseudoacacia stands in the Apele Vii area, the R. pseudoacacia coppice stands at Desa near the Danube River in areas under the jurisdiction of the former Poiana Mare Forest Range Office show excellent growth with a decline grade of 0.4. The No. 17 belt-transect survey plot at Desa is an example of a dune forest of *Populus euroamericana*. Compared to those planted at lowland, the P. euroamericana trees planted at the top of dunes show less favourable growth but most trees have reached a height of 30 m with a low decline grade of 0.3, constituting excellent stands [Fig. 2-4-3-(7) and Table 2-4-8-(7)].

Q. rubra

Q. rubra is a species which was introduced from North America and is regarded as a promising species which can be adapted to southern Romania. This species has been successfully used as roadside trees in Bucharest and its excellent growth in artificial stand at the Retca experimental forest (stand age: 20 years) under the control of Ghimpati Forest Branch Office, Giurgiu Forest Range Office is well-known. The survey findings at a 40 year old plantation site at Perisor UP IV 99A in Dolj County are described in this report.

Such Quercus spp. as Q. frainetto, Q. cerris and Q. robur were planted at the same time at the above plantation site over an area of 7.7 ha. Fig. 2-4-4 shows the survey results on the tree height and DBH of Q. rubra at a survey plot of five lines x 50 m (line interval of 3 m and seedling distance of 1.5 m). The observed tree height and DBH are 15 - 17 m and 20 - 25 cm respectively.

Fig. 2-4-5 compares the tree height of Q. rubra with those of three other Quercus species planted at the same time. The height shown is 15 - 17 m for

Q. rubra, 12 - 14 m for Q. cerris, 9 - 11 m for Q. robur and 7 - 10 m for Q. frainetto.

As described above, the growing state of *Q. rubra* at the Perisor plantation site is far better than that of other *Quercus* spp. The growth of *Q. rubra* at this site must be continually monitored to examine its adaptability to Olt and Dolj Counties.

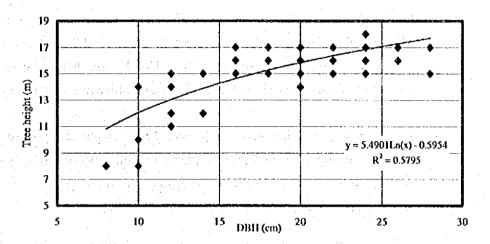

Fig. 2-4-4 Tree Height and DBH (Q. rubra)

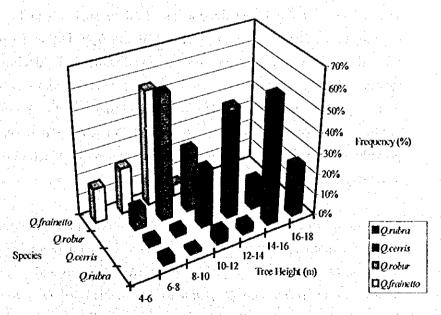

Fig. 2-4-5 Frequency of Numbers of Trees by Height of *Q. rubra* and Other *Quercus* Species

③ Pinus nigra

Pinus nigra is a local species in Romania and its introduction to Olt and Dolj Counties is hoped for because of the little presence of coniferous trees in these counties. Its value as a species for windbreak forests in southern duncs is described in detail in 2.4.6-(1). Here, the survey results on an old plantation site at Topana (Vulturesti UP III 52; stand age of 32 years) are described.

Pinus nigra has the disadvantage of being weak against snow damage. Although the plantation site at Topana shows a good state of growth with an average tree height of 12 m and DBH of 10 - 18 cm, its growth situation must be continually monitored to examine its adaptability to Olt and Dolj Counties.

Topographical consideration to protect *Pinus nigra* from snow damage is particularly important in regard to plantation site selection in order to achieve good planting results. *Pinus nigra* is also a candidate species for hillside regreening work in the future.

4) State of Forest Decline

(1) Forest Decline Fact-Finding Survey

The findings of the forest decline fact-finding survey can be found on the decline survey sheets [App. D-7-(1) - (22)] and App. D-8 and App. D-9 which show the decline grade ratio of the surveyed stands. The decline grade of the surveyed trees was determined as the average measurement results (scores) for four survey items, i.e. tree form, die back, defoliation ratio and branch and leaf density. Such survey items as leaf colour and leaf necrosis can be used to provide useful information on tree health by indicating whether or not trees are adversely affected by disease and pests.

The findings of the fact-finding survey at 22 survey plots are compiled in App. D-6. The main species of declined forests are such Quercus species as Q. frainetto, Q. cerris, Q. petraea, Q. robur, Q. pubescens and Q. pedunculiflora, hybrids of Q. robur and Q. frainetto and hybrids of Q. pubescens and Q. frainetto. Species other than Quercus spp. are Fraxinus excelsior, Fraxinus ornus, Acer campestre and Acer negundo. These broad-leaved species appear at the survey plots mixed with Quercus spp. App. D-6 also lists secondary species observed in declining stands, including those of Quercus spp. which are not considered to be the dominant species, Ulmus minor, Malus sylvestris

and *Pyrus pyraster*. In the case of *R. pseudoacacia*, its state of decline was established based on the tree top death of the surveyed trees at the belt-transect survey plots as described in ② below.

The number of plots with a stand decline grade of 2 or higher is 12 out of 22, i.e. five out of 14 plots in Dolj County and seven out of eight plots in Olt County.

The degree of damage is affected by characteristics of the species. Out of the 22 survey plots, nine plots show a damage degree of "strong". Of these nine plots, Q. frainetto is the dominant species at seven plots. While Q. frainetto often appears mixed with Q. cerris, its degree of damage is always higher than that of Q. cerris which appears to be the least damaged among Quercus spp. A damage degree of "strong" was also observed at one plot each of Q. petraea, Q. robur, Q. pubescens, Q. cerris and a hybrid of Q. pubescens and Q. frainetto. All of these species are often mixed with other species.

Among broad-leaved species other than Quercus spp., Fraxinus excelsior has the highest appearance with a low degree of damage. This species is mixed with Q. robur, constituting stable stands with a high tree height.

Populus spp. tends to show an excellent state of growth with a low degree of damage.

② Die Back of Species Found at Belt-Transect Survey Plots

The findings on the die back of species found at the belt-transect survey plots in the forest vegetation survey are shown in App. D-10 while the ratio by decline grade at these plots as determined by the data on die back is shown in App.D-11.

App.D-10 indicates that *Quercus* spp. belts with a high stand decline grade are plots dominated by *Q. frainetto*. Among the *R. pseudoacacia* plots, those in the area of the former Apele Vii Forest Range Office show a high stand decline grade while those in the area of the former Poiana Mare Forest Range Office show an excellent state of growth with a low stand decline grade.

App. D-11 indicates that six Quercus spp. plots and four Quercus spp. plots have a damage degree of "strong" and "moderate" respectively. Six plots with

a strong degree of damage consist of three plots of forest vegetation type 5 (dominated by Q. frainetto and Q. cerris) and one plot each of forest vegetation type 4 (dominated by Q. petraea), type 10 (dominated by Q. robur and Q. pedunculiflora) and type 11 (dominated by Q. frainetto). All four plots with a moderate degree of damage belong to type 5 (dominated by Q. frainetto and Q. cerris). Two R. pseudoacacia plots in the area of the former Apele Vii Forest Range Office both show a strong degree of damage.

5) State of Defoliation and Acorn Dropping of Q. frainetto

Seasonal observation of defoliation and acorn dropping was conducted at a Q. frainetto-dominated forest at Seaca Optasani and the results are shown in Fig. 2-4-6, Fig. 2-4-7, Table 2-4-11 and App. D-5. This observation used a circular litter trap (1 m² in size) placed below the crown and the trapped litter was measured every month during the period from July to October. The defoliation pattern of Q. frainetto in the growth period in 1998 was not particularly abnormal. The observation of dropped acorns which was conducted at the same time as the observation of defoliation showed only a small number of immature acorns among the collected samples, suggesting normal growth in 1998 as in the case of the defoliation rate.

(2) Composition of Declined Forests

A ground conditions survey and forest conditions survey were conducted at damaged national forests (damaged forests) and forests subject to the avoidance of decline (prevention forests). The survey items were the tree species, tree height, dbh, crown density, decline grade, inclination and slope direction. There are 168 survey plots with a total survey area of 12.16 ha and 8,404 trees. The decline grade classification was conducted mainly featuring the state of dieback while referring to the decline grade evaluation method (Grade 0 through Grade 4) used in Romania for the forest monitoring of single trees [2-4-7-(2)]. The main characteristics of these forests are described below.

- ① Mixed stands of *Q. frainetto* and *Q. cerris* show a high decline grade for *Q. frainetto*. These stands are frequently observed in hill forests in the North Part and in plain forests in the Middle Part.
- ② Mixed stands of Q. petraea, Q. frainetto and Q. cerris show a high decline grade for Q. petraea. These stands are often observed in hill forests in the North Part.
- (3) The relationship between the crown density and decline grade in shown in Fig. 2-4-8. The ratio of declining trees with a decline grade of 2 or high increases as the crown density decreases. However, some plots show a low ratio of declining trees even though the crown density is low. The reason for this is probably that the damage is concentrated on certain species, leading to the removal of declining trees and a resulting decrease of the crown density. Fig. 2-4-9 compares the ratio of trees with a decline grade of 2 or higher with the degree of stand decline. In this figure, the ratio of trees with a decline grade of 4, i.e. dead trees, in the total number of declining trees is shown for each survey plot. Obviously, sound stands have a low ratio of trees which are judged to have a decline grade of 4. When the ratio of declining trees with a decline grade of 2 or higher increases, the ratio of trees with a decline grade of 3 or 4 among the declining trees becomes high. This fact indicates that the ratio of trees with a high decline grade increases with a higher ratio of declining trees. Stands with a crown density of 60% or more are generally judged to be healthy. However, stands of more than 100 years of age show a low crown density level because of the proximity to the rotation age. In the case of these stands, no close correlation between forest decline and the crown density is observed. These stands also show little damage due to drought. When the crown diameter of declining trees is compared with that of healthy trees, the crown diameter of the former is smaller under a similar stand density, resulting in a tendency towards a lower crown density at declining stands.

- ① Declined forests are mainly observed in forests of 40 years of age or more. Young stands show rather little damage.
- (5) There is no distinct correlation between herbal undergrowth and forest decline. At those sites where the crown cover is opened up due to the disposal of damaged trees, however, herbs of *Gramineae* tend to become dominant, often preventing regeneration by natural seeding.
- (6) Trees with advanced decline at the crown are further suppressed by neighbouring healthy trees and, therefore, their height tends to be lower than that of healthy trees.

The results of the forest conditions survey are shown in App. D-13.

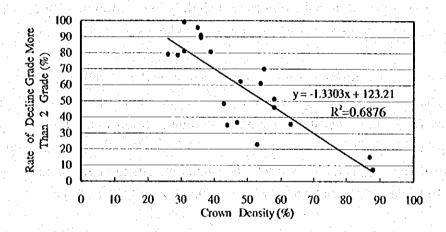

Fig. 2-4-8 Relationship Between Rate of Decline Grade 2 or Higher and Crown Density

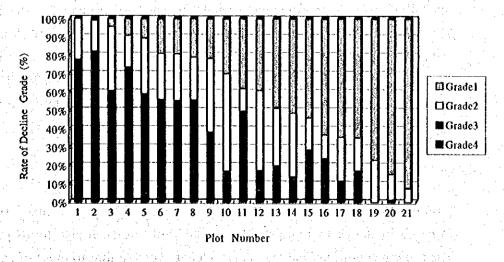

Fig. 2-4-9 Rate of Declining Trees by Survey Plots

Based on the above survey findings on the forest structure, the interpretation of declining stands on the aerial photographs was conducted and the interpretation results are described in 2.6.2.

(3) Growth of Main Species and Phenology

A general forest conditions survey, analysis of the collected reference materials and interviews with local forestry engineers were conducted to establish the picture of growth of the main species which is described next.

Quercus robur

This species is suited to a climate of continental diversity. Its resistance to winter cold is fairly strong but due to its strong demand for a certain temperature during the growth period, it is distributed at a slightly lower altitude than *Q. petraea*. It is often distributed in areas with good water conditions, such as flood plains.

Quercus robur forms the upper story canopy and is a tall tree which eventually reaches a high of 30 - 35 m with a dbh of 1 - 2 m. Growth is at the maximum between 50 and 70 years of age and it continues to grow for 150 - 200 years. The expected life is as long as some 500 - 600 years. Provided that the soil and other growth conditions are favourable, the annual increment is 7.5 m³ per ha for a stand of 100 years of age and 9 m³ per ha for a stand of 120 years of age.

Quercus cerris

(Forest and grassland forest) This species is found in steppe forests, plain forests and hill forests. Apart from pure stands, it tends to form mixed stands with *Q. frainetto*. It withstands hot weather, low precipitation and drought. It can reach a height of 35 m with a dbh of 1.5 m. Although the annual increment is lower than that of *Q. robur* and *Q. petraea*, it is higher than that of *Q. frainetto*. The average annual increment reaches 5 m³ per ha at an age of approximately 100 years with favourable growth conditions.

③ Quercus frainetto

(Forest and grassland forest) While this species often forms mixed stands with *Q. cerris* in steppe forests, plain forests and hill forests, it also forms pure stands. The growth conditions and tree shape, etc. are very similar to those of *Q. cerris*. Its distribution area, however, tends to be at a higher altitude than that of *Q. cerris*. In

general, it withstands compacted soil better than Q. cerris but its resistance to drought is lower than that of Q. cerris.

The growth performance of Q. frainetto is slightly inferior to that of Q. cerris and the most vigorous growth is observed at an age of around 100 years with an annual increment per ha of approximately 4.5 m^3 per ha with good growth conditions.

The existing natural stands have more often than not been generated by coppicing from the roots rather than ordinary coppicing and this is considered to be one reason for the poor seed bearing in recent years. Q. frainetto is the only Quercus species capable of regenerating by coppicing from the roots.

Fraxinus excelsior

This species is not particularly suited to compacted soil. It is often mixed with *Q. robur* and forms the upper story canopy together with *Q. robur* and *Tilia platyphyllos*. It is a tall tree reaching a height of some 40 m with a dbh of 1 m. The initial growth is larger than that of *Q. robur* and the maximum growth is achieved at an age of 30 - 40 years. Growth after 70 - 80 years of age is inferior to that of *Q. robur*. At the best of the experimental sites, the annual increment may reach 8 - 10 m³ per ha. Special care is required during the tending stage of mixed stands because of the fast initial growth.

(5) Robinia pseudoacacia

This species withstands drought better than Q. frainetto but is unsuited to compacted soil, preferring soil with a high porosity. It can reach a height of 25 - 30 m with a dbh of 80 - 100 cm. The initial growth is exceptionally large, reaching a height of 10 m in five years but the growth starts to decline after 15 - 20 years. The annual increment is around 15 - 17 m³ per ha for a 20 year old stand.

⑥ Populus euroamericana

This species enjoys strong initial growth and the annual increment reaches a maximum of approximately 30 m³ per ha at an age of 15 - 20 years. It eventually reaches a height of 40 - 50 m with a dbh of 2 m.

The phenological aspects such as flowering and seed bearing, etc. of the main species are shown in Table 2-4-12. Phenological information on flowering and seed

bearing, etc. can constitute indices to judge the appropriate timing for various types of work for successful regeneration by natural seeding and nursing.

2.4.4 Forest Land Productivity

(1) Forest Land Productivity

Tree growth is determined by the tree height and thickening growth while stand growth is determined by the stand density of forest trees. It has been theoretically established that thickening height is closely related to the stand density when a stand is stratified by tree height. Thickening growth is, therefore, a factor which must be taken into consideration when analysing the stand structure. As the stand structure is characterised by the type of forest work operation, thickening growth should be understood as a factor determined by the type of forest work operation. In contrast, as far as tree growth is concerned, the tree height tends to act as an independent variable, i.e. a factor less affected by the type of forest work operation. The site index is an index determined by this tree height as an independent variable. When considering the purpose of use (rotation age) and the height growth curve of *Quercus* spp., the main species in the Study Area, it is deemed appropriate to treat the height of 100 year old trees as the site index.

The height of such coniferous trees as *Picea* spp. and *Cedrus* spp. is closely linked to the water environment of the soil and is generally high along valleys and low along ridgelines in mountain areas. In comparison, such correspondence to the water

environment is not so clearly shown by broad-leaved trees, forming the common opinion that the impacts of the water environment, i.e. topographical location in a valley or on a ridgeline, on them are small. However, a close relationship between topographical features and the water environment is observed in the case of *Quercus* spp. stands in the Study Area. The Study Area generally consists of terraced fans with a thick gravel layer and low annual precipitation of 500 - 700 mm. At relatively high middle terraces as well as high terraces, the deep groundwater level suggests that the soil is always dryish. Low terraces of which the relative height from the groundwater level is rather small, however, enjoy a comparatively wet environment.

The compact bed soil formation in the Study Area has been believed to be a negative factor for plant growth. Because of such compactness, however, a capillary system consisting of fine pores is well developed in this formation and it is assumed that a large quantity of water is stored in these fine pores. As the capillary tension of fine pores is strong, it is not easy for trees to use the water stored in the fine pores. Nevertheless, a poor but stable water environment is available for forest trees which are capable of extending their root systems in this compact formation. The survey results indicate that *Q. frainetto* and *Q. cerris* are species which can adapt to such a compact formation.

Meanwhile, areas with different site qualities can be found on the surface of terraces above the compact formation as their water storage, infiltration and drainage conditions reflect the existence or non-existence of A and B horizons with a different thickness as well as degree of swelling and softness (compactness) and also slight but still differing inclinations and undulations.

More detailed analysis reveals that Class I and Class II sites of Q. robur are located in an environment (low terraces, etc.) with abundant water stored in medium and fine pores (pF < 2.7). In contrast, Class III through Class V sites where Q. frainetto and Q. cerris often grow present an environment where water stored in the fine pores in the compact base soil formation can be utilised. Using the site quality of Q. frainetto sites as a criterion, Class I Q. robur sites are above this criterion and Class II Q. robur sites closely resemble Class I Q. frainetto sites. The relationship between the site indices for Q. frainetto and Q. cerris and the land conditions is outlined in Table 2-4-13.

and for my more legislates, and for the similar of many in the second of the second of

Table 2-4-13 Site Indices (Tree Height of 100 Year Old Stand) for Q. frainetto and Q. cerris and Land Conditions

Site Quality	Tree Height (m)	Land Conditions
Special I	30.1 - 34.0	- Low terraces with swollen and soft A and B horizons
I	26.1 - 30.0	- Low terraces; slightly compact A and B horizons in the case of Q. robur
H	22.1 - 26.0	- Slopes with thick soil or weathered layer; compact low terrace
Ш	18.1 - 22.0	- Terrace surface with gentle inclination, minor undulations and good drainage - Flat surface of middle and high terraces with swollen and soft A and B horizons
IV	14.1 - 18.0	- Flat surface of middle and high terraces with crown coverage of approximately 60%
V	10.0 - 14.0	- Flat surface of middle and high terraces covered by compact A and B horizons
	el production and	- Narrow terraces with low level of water stored in fine pores - Forest edges and windy sites with crown coverage of 50%

Notes

Special I

Class I Q. robur site

Thickness of A horizon

healthy forest land = 15 - 20 cm; poor forest land = <15 cm

Depth of B horizon

healthy forest land = 25 - 30 cm; poor forest land = very compact below 5 - 15 cm

Analysis of the relationship between declined forests and site quality shows that conspicuously declined forests are overwhelmingly found at site index Class V sites, followed by Class IV and are rare at Class III sites. When the ground surface is compacted due to trampling, associated with stock raising, it loses large and medium pores, resulting in a considerable decline of the air permeability. In particular, if the B horizon is compacted, even the fine pore ratio is reduced, forming an impermeable layer. Under such circumstances, the water which infiltrates the A horizon loses the ability to coexist with air, becoming stagnant water lacking oxygen. As a result, the physiological activities of fine roots are hampered, resulting in root decay. At those sites where the surface soil is compacted, this obstruction occurs every time it rains, producing chronic poor forests. The latest phenomenon of decline occurred when such chronic poor forests reached the stage of decisive decline due to drought damage. At forest land of Class V site quality, there are some healthy stands despite their small increment. However, stands at Class V sites are often poor because of the very compact top soil layer.

(2) Site Index Distribution

The area of forests and damaged forests by site index and forest range office in each geographical area for *Quercus* spp. and *Robinia pseudoacacia* which are the main species in the Study Area is shown in Table 2-4-14. Meanwhile, the area of forests and damaged forests by site index and forest range office in each geographical area for all species is shown in App. B-2. As the area figures used in these tables are quoted from the

forest management book of each forest range office, they differ from those used in this report. The site index distribution by species as well as by geographical area is described next.

In the North Part, although the area of damaged forests is small, the proportion of damaged forests with low productivity (V) is high in the case of *Quercus* spp. forests. These forests are mainly located on slopes in hilly mountain foot areas.

In the Middle Part, damaged forests with low productivity cover a wide area. Many of these forests are plain forests which are dominated by *Quercus* spp. at middle and high terraces. Forests which are dominated by *Quercus* spp. and located on gentle slopes show a high proportion of medium productivity (III) forests.

In the South Part, the proportion of damaged forests with low productivity is slightly high. Many of these forests are located on dunes in the plain sections of low and middle terraces and are dominated by *Robinia pseudoacacia*. The forests at low terraces show a high proportion of forests with high productivity (I and II).

2.4.5 Yield Tables

The Study is characterised by the use of the crown coverage ratio, which can be interpreted on aerial photographs as the parameter. What are basically required to identify the forest mechanism and its secular changes and to predict its future are yield tables. The preparation of yield tables using the crown coverage ratio as the parameter is, therefore, essential for the financial and economic analyses for the Plan. As a highly accurate yield table was available for each species or variety in Romania, these tables were used as basic reference materials for the preparation of yield tables which use the crown coverage ratio as the parameter by means of their re-interpretation. The evaluation of declined forests also requires yield tables by decline grade. Accordingly, yield tables for declined forests using the crown coverage ratio as the parameter were prepared.

Re-interpretation of the yield tables was basically conducted using the growth analysis technique based on the crown form model. The decision on the parameter values was crucially important and, therefore, the trial and error process was repeated several times to decide these values while referring to the field survey data. As fine analysis was omitted, the results appear to slightly lack accuracy. Nevertheless, they are considered practically reliable without any contradictions.

A typical yield table example for Q. frainetto resulting from this exercise is shown in Table 2-4-15. The yield tables for the main species and the concrete analysis method are shown in App. E-3. Particularly important points are explained below.

- As the crown coverage ratio in the yield tables for Class V Q. frainetto and Q. cerris sites is roughly 50% with a relative stance (SR) of some 25%, the yield at these sites is evaluated as being similar to that of a crown coverage ratio with a damage degree of "weak". Although the tree density is restricted to low to mitigate competition for water at dry land, the relative stance of 25% is a figure which makes crown closure possible. Consequently, the low crown coverage ratio is assumed to be attributable to the site characteristics rather than forest management.
- In each site index area, the crown coverage ratio is maintained at the level of crown closure, i.e. 60% or higher, upto 100 years of age. Opening of the crown due to aging begins to appear between 100 years (low site index areas) and 120 years (high site index areas). The crown coverage ratio is low in the case of young forests of 50 years of age or less. As this is the period of most vigorous growth, the low crown coverage ratio is a contradictory result when compared with the normal state of crown growth, indicating problems in regard to the measurement and analysis methods used in compiling the yield table.

2.4.6 Environmental Conservation Functions of Forests

(1) Forest Functions

Forest functions are principally classified as functions of producing timber as a resource (resource production functions) and functions of conserving the natural environment (environmental conservation functions). The environmental conservation functions of forests are analysed here.

There are seven forest functions related to environmental conservation in the Study Area, i.e. water conservation function, windbreak function, soil conservation function, climate mitigation function, wildlife protection/preservation function, recreational use and landscape maintenance function and CO₂ fixation. These seven environmental conservation functions are summarised next.

1) Water Source Conservation Function

The water infiltration performance of the top layer is crucial for the infiltration of rainwater into the ground and its subsequent storage in the soil and bedrock formations. That this infiltration rate is high in forests and low in other areas of land use is known to be a serious problem. With the advancement of forest exploitation to reduce the relative ratio of the forest area, the water source conservation function of forests declines. Therefore, when the ratio of forest area is high, it is judged that the water source conservation function of forests is strong.

Concrete analysis and evaluation of this function requires a flow rate survey on rivers and groundwater in the watershed. For the present study purposes, a rough estimate was made using data on the infiltration capacity of the top layer (0 - 5 cm), infiltration capacity at 25 cm below the ground surface and dam inflow.

Table 2-4-16 shows the infiltration capacity per minute (mm/min) of the top layer obtained by a simplified cylindrical infiltration gauge during the field survey. The numerical values shown in the table are real measurement values which are excessively large compared to the state of infiltration at the time of actual rain. The measured values are large because they reflect forced infiltration under pressure in a closed system. Empirically, such values are thought to be some 25 times higher than the real value. Following this line of thought, the infiltration capacity per hour is estimated to be some 2.4 times higher than the observed infiltration capacity per

minute. As such, the measures values of the infiltration capacity are problematic but can still be effectively used as comparative values.

An infiltration structure consisting of medium and large pores is formed in natural forest soil by the vigorous ploughing activities of soil animals and others and an infiltration capacity of more than 60 - 70 mm/hr can be observed. This infiltration capacity level is high enough to infiltrate entire rainwater. However, when the measured values in the table are converted to the infiltration capacity per hour by multiplying them by 2.4, the minimum and maximum values fail to reach 10 mm/hr and 40 mm/hr respectively at many plots, indicating a low infiltration capacity. The infiltration capacity of the B horizon immediately below the top layer in particular is less than 10 mm/hr at all plots, indicating extremely unfavourable infiltration conditions. The major reason for such a low infiltration capacity is the fact that the subject soil formation is a clayey-silt formation under an almost semi-arid climate with low rainfall.

Table 2-4-16 Infiltration Capacity of Top Layer by Land Use and Soil Type

Sil	e	Infil	ration Capac	ity (mm/i	nin)
Land Use	Soil Type	Median	Min	Max	No.of Sites
Forest Land	LV	4.1	1.3	15.9	18
	FL	9.0	1.6	27.0	10
	CH	24.0	9.3	25.9	4
	PH	29.7	29.4	30.0	2

	CH	3.0	2.0	6.8	4
Grassland	LV	2.2	2.2	2.2	2
	FL	22.6	22.6	22.6	ı

During the fifth field survey period, the infiltration capacity at 25 cm below the top layer was measured at 13 plots in typical forests in Olt and Dolj Counties to compare it with the infiltration capacity of the top layer and also to verify the suitability of the planned drainage and infiltration works. The measurement results are shown in Table 2-4-17. The infiltration capacity at 25 cm below the top layer is fairly small at some 15% of the infiltration capacity of the top layer. However, the range of values from several 10s to several 100s mm/hr suggests that the planned drainage and infiltration channels to be placed at this depth should sufficiently perform the intended function.

One important soil index in connection with water resources is the size of the water storage capacity of the soil formation. As the storage capacity is equivalent to the quantity of coarse pores (pF 0.6 - 2.7) in the soil formation, such a quantity within a 1 m deep soil formation is calculated. The water storage volume (Ss: mm) is expressed by an integral of porosity of pF 0.6 - 2.7 and the thickness of each horizon.

Table 2-4-17 Infiltration Capacity at 25 cm Below Top Layer at Forest Land

Note: 1) The soil hardness was measured using Yamanaka's soil hardness meter.

$$\Theta i = \Theta(0.6) - \Theta(2.7)$$

 $S_s = \Sigma \Theta i \cdot Hi$

 Θ i: porosity of pF0.6 \sim 2.7 (%)

Hi: thickness of each horizon (mm)

Table 2-4-18 shows the calculation results of the water storage volume per 100 cm of soil thickness using a horizon thickness of 15, 45 and 40 cm from the top layer to the lower horizon and the porosity of each layer (horizon). Soil porosity by survey point is indicated in App. A-7.

The storage capacity of coarse pores shown in the table ranges from 30 mm to 80 mm and is not particularly high. In fact, it is extremely low compared to the normal storage capacity of forest soil under a wet temperate climate at 200 mm/m or higher. As described in 2.2.4-(1) of the Study Findings, trees in the Study Area are inferred to be using water stored in not only coarse pores but also fine pores. The combined water storage capacity of coarse and fine pores is 200 - 400 mm/m, at last reaching the level of the expected water storage capacity under a wet temperate climate.

The porosity of forest soil linked to the water conservation function in the Study Area is rather poor as discussed so far but is still far better than the porosity of farmland, making it desirable to increase the forest area in order to improve the water resource situation in the Study Area. The ratio of forest area at highland and tableland of around 7% is low and the reality is that there is concern in regard to a further decline of the forest area. At tableland, groundwater is used as household water and farming water and its stable use poses an important task. Moreover, forest trees use water stored in the bed formation and the improvement as well as preservation of the water conservation function of forests is hoped for to ensure the smooth growth of forest trees. At tableland, it is possible to use underflow water from major rivers because of its being formed on top of a fan if boreholes of 100 -150 m in depth are constructed. However, such boreholes pose technical as well as cost-related difficulties. It is, therefore, important to use shallow groundwater stored in the tableland itself. In short, improvement of the water conservation function of forests in the entire Study Area is highly desirable to achieve the stability and maintenance of shallow groundwater and water stored in the bed formation.

2) Windbreak Function

(1) Preservation of Wind Conditions

According to statistical data on the wind direction and velocity (Climatological Atlas; statistics for 15 year period from 1941 to 1955), areas exposed to strong wind are the southern part of Olt County from Caracal to Corabia, and the central and southern parts of Dolj County including Craiova. During the farming period from spring to autumn, these counties are exposed to strong wind of 3 - 6 m/sec on average (based on statistics for the 30 year period from 1967 to 1997; see 2.2.1). The prevailing winds are the western and eastern winds throughout the year. An area of which the average wind velocity exceeds 3 m/sec is usually said to require windbreak forests for farming purposes.

Even in the case of gently sloping terraces or highland topography with ridge-like convex slopes, it is known that the wind velocity reaches its maximum at such convex slopes, particularly sites of high exposure. As far as high terraces and highland areas are concerned, therefore, the establishment of forests, particularly on ridge-like gentle slopes, is important to ensure gentle wind conditions.

It is often the case that the frequency of wind in a certain direction is especially high in some areas. If a specific wind direction prevails, valleys or passes parallel to this direction are subject to particularly strong wind. A wide forest spreading from a valley to overhanging slopes is required to break this kind of strong wind.

② Necessity for Windbreak Forests

In general, wind faster than 3 m/sec is said to be harmful to the growth of agricultural crops. A strong spring wind not only causes wind erosion by blowing away the top soil of farmland but also blows away or damaged the sown seeds and transplanted seedlings. According to a report published by the Sand Crop Research Institute located in Dabuleni in the South Part of Dolj County, the roots of crops are exposed due to wind erosion and leaves suffer mechanical damage in areas subject to strong wind. The same report states that the loss of top soil is particularly severe in spring and that a flying sand volume of 10 tons per ha can be observed. Meanwhile, the Slatina Forest Range Office reports that as much as 500 ha of farmland was once damaged by wind in the South Part of Olt County. There has also been a report urging the future

creation of a windbreak tree belt in the strong wind zone extending from Sadova in the South Part of Dolj County. The mean annual wind velocity in the South Part of Olt County is 3.2 m/sec with a western prevailing wind during the farming period and an eastern prevailing wind in winter. In areas where wind with a mean velocity of 3 m/sec or more prevails, local forests are expected to perform the function of a windbreak. The interview survey discovered a case where the productivity of farmland which had been converted from forest land declined due to wind damage resulting from the loss of trees. In another case, an irrigated farming system using irrigation channels was forced to recreate a forest (windbreak forest) as its productivity had declined due to wind damage resulting from the construction of irrigation channels by cutting forest trees.

③ Types of Windbreak Forests

According to the Forest Planning formulated by the former Corabia Forest Range Office in Olt County, windbreak forests in Olt and Dolj Counties can be classified into the following six types based on their function and objective.

- Type 1: Main tree belt windbreak tree belt with a width of 7.5 m and an interval of 280 m to prevent wind damage to farmland
- Type 2: Supplementary tree belt tree belt of 7.5 m in width to protect an irrigation channel from flying sand
- Type 3: Main water channel protection tree belt tree belt of 8 20 m in width to protect slopes along a main water channel
- Type 4: Settlement protection forest tree belt of 10 30 m in width to protect a settlement from strong wind
- Type 5: Road protection forest tree belt of 10 20 m in width to protect a road from strong wind and flying sand
- Type 6: 50 m wide tree belt 50 m wide tree belt to protect an irrigation system

Examples of these six types of windbreak forests in Corabia located in the South Part of Olt County show that Type 1 forests to protect farmland account for more than half of the total windbreak forest area (99 ha out of 194.5 ha), followed by Type 4 forests (30 ha) and Type 3 forests (26 ha). The main species of these windbreak forests are R. pseudoacacia and P. euroamericana.

(4) Windbreak Forest Fact-Finding Survey

There is a well-developed network of windbreak forests in Sadova in the South Part of Dolj County, a neighbouring area of Corabia in the South Part of Olt County. The total area of windbreak forests under the jurisdiction of the Sadova Forest Range Office is 793.5 ha and R. pseudoacacia and P. euroamericana are the two main species. In addition, Pinus nigra is planted as a coniferous species. A windbreak forest fact-finding survey was conducted on these three species.

a) Populus euroamericana Windbreak Forests

The local standard specifications for a windbreak forest to protect farmland are a width of 7.5 m and an interval of 280 m between tree belts. At the relevant survey plot, *Populus* spp. is planted in two lines with a 4 m interval between the lines and a 3 m interval between the trees. Two lines of *Elaeagnus angustifolia* are planted along the edge of one side. The *P. euroamericana* trees at the survey plot are approximately 27 years of age with a tree height of 25 - 27 m and a dbh of 40 - 50 cm and their state of growth is fairly good. Although the decline grade of the planted trees of around 1 is low, damage due to defoliators can be observed [Fig. 2-4-10-(1) and Table 2-4-19-(1)].

Elaeagnus angustifolia which is planted at the edges of *P. euroamericana* stands forms a bush with a height of 3 - 4 m, preventing ground wind. The standard distance of 280 m between windbreak tree belts is approximately ten times the height of *P. euroamericana* and coincides with the maximum distance of windbreaking effect.

b) Robinia pseudoacacia Windbreak Forests

The R. pseudoacacia windbreak tree belt in question protects experimental farmland of the Sand Crop Research Institute in Dabuleni, an area under the jurisdiction of the Sadova Forest Range Office. The tree belt consists of four lines of trees with a distance of 1.5 m between the lines and 1.5 m between the trees. In addition, two lines of Elaeagnus angustifolia are planted along the forest edge. Many R. pseudoacacia trees have been generated by coppicing and the stand age survey using an increment borer suggests a stand age of approximately 25 years. The tree height ranges from 5 m to 10 m while the DBH ranges from 10 cm to 40

cm, showing a large growth discrepancy between individual trees. The decline grade is 2 and many declined trees have already been felled [Fig. 2-4-10-(2) and Table 2-4-19-(2)].

c) Pinus nigra Windbreak Forests

P. nigra is an indigenous species found in the West Part of the county neighbouring Dolj County. The environment of this habitat is sub-alpine with gravelly soil and this species is used for revegetation to restore landslide sites in the area. The surveyed tree belt constitutes a windbreak forest to protect the experimental farmland of the Sand Crop Research Institute at Dabuleni. P. nigra is densely planted in four lines with a distance of 1.5 m between the lines and 1 m between the trees. Along the windward edge of this P. nigra tree belt, Elaeagnus angustifolia is planted. Many of the P. nigra trees grow in the 5 - 8 m tree height class, showing a decline grade of 1 or 2 [Fig. 2-4-10-(3) and Table 2-4-19-(3)]. This P. nigra tree belt is believed to constitute a silviculture indicator for the future introduction of coniferous species in the Study Area.

3) Soil Conservation Function

Surface flow and soil erosion occur at places with a low infiltration capacity. As in the case of the water conservation function described earlier, soil erosion is small in watershed with a high forest area ratio and a low ratio of farmland area. In the opposite case, soil erosion is judged to be large. It is, therefore, necessary to locate forests with a high infiltration capacity at sites where eroded soil is discharged to a river in order to prevent turbid water.

In those places where a river is carving mid to high terraces, steep slopes of more than 35° (terrace scarps) are formed, causing landslides (watershed of Scorburoaia River and Dejasca River, both tributaries of Olt River). As terrace scarps lack a bedrock layer, their conditions slightly differ from ordinary mountain land. If the slopes of these terrace scarps are covered by forests, it is believed that landslides are less likely to occur. As the use of steep slopes for purposes other than forest land is difficult, the conservation of steep slopes as forest land to prevent slope failure is required.

4) Climate Mitigation Function (Preservation of Living Environment)

Forests contribute to the conservation of the living environment for humans. Many villages (Cosoveni and Criva, etc.) in the Study Area are adjacent to forests and local forests function as a shield vis-a-vis emission gas from factories and automobiles. Any progress of forest decline damages this forest function. Sound forests must, therefore, be preserved or restored.

5) Wildlife Protection and Preservation Function

Forests provide a much richer habitat for wildlife than such other types of vegetation as grassland and farmland. The existence of forests with diverse species and a high forest area ratio means rich flora and fauna, preserving a complicated food chain which includes natural enemies.

Many forests were felled in Western Europe from the 18th century to the early 19th century to expand farmland and grazing land. As a result, there was a great population explosion of field mice and other pests. Learning from this experience, the restoration of forests earnestly commenced in the late 19th century, achieving a forest area ratio of more than 15%, even on plains, in the 20th century. However, the forest area ratio in the Study Area is still as low as

some 10%, making at least the maintenance of the present forest area necessary in order to allow forests to function adequately.

6) Recreational Use and Landscape Maintenance Function

Landscape is something which is aesthetically evaluated by humans. Forests, which are harmonious from the viewpoint of natural science, present an excellent landscape. As such, a forest group (defined in terms of the composition of species, area size and forest layout) which maintains harmony with the natural ecosystem, a forest group with an excellent water resource conservation function and a forest group with an excellent windbreak function, etc. are also highly evaluated as landscape forests. These forests must, therefore, be preserved or restored.

7) CO, Fixation

The CO₂ fixation by forests and wood is attracting much attention in recent years from the viewpoint of preventing global warming. The problems associated with CO₂ emission pose an unavoidable challenge for advanced manufacturing, mining and other industries and strong interest is expressed in forest creation as a measure to reduce the adverse impacts of CO₂ emission. To be more precise, planning is in progress to design and create forests with these industries bearing part of the cost. In an age when funding for afforestation poses a stiff challenge for forestry which is in a difficult financial situation, such planning is a welcome trend to be exploited for the extension of forests. Forests designed to produce durable timber not only fix CO₂ during their growth period but also maintain CO₂ fixation in the form of harvested wood. As such, wood is considered an advantageous material to deal with the problem of CO₂ emission.

Among existing forests in Olt and Dolj Counties, the area by site quality and damage grade was established for conspicuously damaged *Quercus* spp. forests and *Robinia pseudoacacia* forests to calculate the CO, fixation volume. In addition, the volume of CO, fixation at existing forests and declined forests (converted based on the volume at final cutting) was calculated to roughly estimate the monetary value. The calculation results are shown in Table 2-4-20. The line of thinking for CO, fixation calculation is explained in App. E-5.

The CO₂ fixation volume of forests consisting of fast growing species where harvesting and regeneration are frequently conducted is not necessarily high. These forests may be disadvantageous unless they can show high profitability as every regeneration incurs an expense. In this context, *Quercus* forests, particularly healthy forests of Class IV or higher, can be valued as having a good CO₂ fixation function as well as being profitable.

Table 2-4-20 Qualitative Fixation Ability in Existing Forests and Declined Forests

(2) Forest Function Groups in Romania

Forest functions are classified into several groups in Romania as shown in Table 2-4-21.

Table 2-4-21 Forest Function Groups in Romania

Group	Sub-Group	Name	Description	Remarks
1: Fore	st with Special	Protection Function		
•	rests with water nservation funct		Forests located near sources of drinking and industrial water, etc.	la - li
•	rests with soil anservation funct		Forests at devastated land, flying sand zones and swamps, etc.	2a - 2l
vis	rests with protest climatic factors llution, etc.	ction function vis-a- s and industrial	Forests protecting farmland and roads, etc. and forests in areas of air pollution, etc.	3a - 3k
4) Po	rests with recrea	ational function	Porests with forest park and recreation function, forest to protect and develop hunting resources	4a - 4k
		tific function vis-a- vironmental sources	National park, natural park and forests to protect genetic and ecological resources	5a - 51
2: For	ests with Protect	tion and Production F	unctions	2.0a - 2.0c

Source: Norme technica pentru amenajamentul silvice (1986)

Of the two groups shown in Table 2-4-21, Group 1 consists of forests which are expected to perform the environmental conservation function while Group 2 consists of forests which are expected to perform the resources production function in harmony with the environmental conservation function. As the environmental conservation function is further classified into sub-functions (sub-groups), the designated functions of forests in the Study Area were listed and certain functions were combined based on their similarity. Accordingly, the use of the groups shown in Table 2-4-22 is deemed appropriate to establish the forestry activity (forest management method) and to conduct the functional evaluation of forests for the Plan formulation purposes.

Table 2-4-23 shows the area of forests, area of damaged forests and ratio of damaged forests by forest function category in Olt and Dolj Counties based on the above functional categories. In this table, a large damaged area can be observed with *Quercus* forests in hilly areas (1.3C), timber production forests (2.0B) and windbreak forests (1.2G), etc. while a high proportion of damaged forest area in the total forest area can be observed with *Quercus* forests in hilly areas (1.3C), windbreak forests (1.3K), recreation forests (1.4I) and seed forests (1.5H), indicating the importance of *Quercus* forests in hilly areas in the Study Area.

Table 2-4-22 Grouping of Forest Function for Formulation of Forest Restoration Plan

Forest Function Under the Plan		Porest Function Group in Romania ¹⁾

	1.5j	Old-age forests of special value; forests with rare species	ii
10. Seed Stands	1.5h	Seed stand; tree genetic resources conservation forest	11

Note: 1) As only forest functions relevant to Olt and Dolj Counties are listed here, this table is not an exhaustive list of forest functions regulated by RNP.

²⁾ The following operation standards by forest function apply in Romania.

- Forests with special environmental conservation functions
 Cutting is prohibited in these forests without a permit issued by the competent organization under the Environmental Protection Law (trees may be cut and used for research purposes as an exception).
- II. Forests with special environmental conservation functions

 These forests are located in places characterised by ecological difficulty and cutting is not allowed under ordinary regulations. Special conservation work is conducted in these forests in accordance with the instructions clearly given by the Romanian Forests Planning. (The only permitted activities are 1) special forest conservation work in response to the specific conditions of forests to improve the environmental conditions and protection function and 2) cutting to control damage by diseases and pests.)
- III. Porests with special protection functions (functional categories of 1.1B, 1.1G, 1.3I, 1.4B, 1.4D, 1.5B and 1.5I) Intensive management, selective cutting and/or semi-selective cutting are permitted in these forests depending on the inclination of the forest land. If the inclination is 25° (30°) or more, special conservation work is conducted.
- IV. Forests with special protection functions Other types of operation may apply under a certain regulatory regime at these forests and selective cutting or semi-selective cutting is permitted.
- V. Forests with special protection functions as well as production function These forests supply high quality wood and selective cutting, semi-selective cutting or group selective cutting is applied.
- VI. Forests with special protection functions as well as production function All types of operation may apply at these forests, taking the ecological conditions, socioeconomic conditions and management conditions in that order into consideration.

Note: The figures for All Forests differ from those used in the present Report as these are the figures given in the forest management plans for the forest range offices.

(3) Positive Effects of Forest Functions Other Than Wood Production

The field survey in the first year found such functions other than wood production, including fuelwood, in the Study Area as the harvesting of forest by-products, provision of hunting grounds and sites for apiculture, windbreaking, water source conservation, soil conservation and the preservation of forest landscape, etc. The current conditions of these functions were surveyed together with a socioeconomic survey through interviews with field staff of the RNP, village heads and representatives of farmers. The results of these interviews in the North, Middle and South Parts are summarised in App. C-2. Of these functions, those providing direct revenue for the RNP are listed in Table 2-4-24.

Source: RNP

Forest by-products include the small fruit of shrubs, medicinal herbs, mushrooms and fodder grass, all of which grow naturally in forests. The RNP employs local people on a daily wage basis to collect and sell these by-products to earn revenue. Local people are permitted to collect small quantities of these by-products for their own consumption. Therefore, forest by-products benefit local communities by means of providing waged labour and supplying household needs. Of the RNP's sales income of approximately US\$ 92,000 in 1998, some US\$ 68,000 was paid to local people in the form of wages.

Hunting is conducted in almost all forest areas and surrounding fields. The RNP and the General Association of Hunting and Fishery (AGVPS) conduct surveys on wild birds and animals and activities to assist breeding through feeding and to protect them. They make financial gains by collecting a fee from hunters for hunting permits and selling the meat of the wild animals received from hunters. The estimated income of the RNP and AGVPS in 1998 was some US\$ 207,000 and US\$ 187,000 respectively.

The RNP and AGVPS also charge a fee for fishing in inland waters. Another source of income is the culture of such fish as trout. These fishery activities are possible because of the contribution of forests to a stable supply and the purification of river water which must be counted as one of the conservation effects of forests. The estimated income of the RNP and AGVPS in 1998 from fisheries was some US\$ 28,000 and US\$ 14,000 respectively.

Apiculture relies on honey bees which are attracted to the flowers of various trees, shrubs and herbs growing in forests. R. pseudoacacia and Tilia platyphyllos are particularly useful species. The figures shown in the above table indicate the direct revenue of the RNP from apiculture. In addition, the Apiculture Association alone has more than 3,000 local members. In the case of R. pseudoacacia and Tilia platyphyllos forests, 4 - 5 bechives can be installed per hectare with each bechive producing some 19 kg of honey in spring. In summer, apiculture is conducted in sunflower fields with each bechive producing some 40 - 50 kg of honey. The producer price of honey in 1998 was approximately US\$ 1.8/kg. The honey production value of the RNP in 1998 was US\$ 42,000 which was earned by the former Slatina Forest Branch Office. The total production value of private apiculturists was some US\$ 1,037,000, the spring production value of which accounted for some US\$ 438,000, indicating the relatively large economic effect of local apiculture.

Even though the RNP earns income from various sources, the large costs of each activity has reduced the profitability. Consequently, the RNP is planning to transfer the production of forest by-products and honey, craftwork and fish culture, etc. to the private sector so that it can concentrate mainly on forest management, such as wood production and the control of wild birds and animals.

The windbreaking effect of forests on farmland, etc. is strongly recognised by farmers in the southern areas of both counties. The spread of sandy soil from the riversides of the Danube to low tableland areas and the dry climate mean that strong wind causes flying sand, damaging not only crops but also the farmland itself. In view of the importance of windbreaks, more than 16,000 ha of windbreak forest belts have already been established using *P. pseudoacacia* and *Populus* spp., contributing to farming activities together with the remaining forests in the form of consolidation. Farmland between these forest belts mainly produce wheat, maize, sunflowers, melons and grapes. The fact that none of these can be cultivated without windbreak forests due to strong wind and flying sand shows the important windbreaking effect of forests.

The water source conservation function of forests is not well recognised by local people, because of the fact that most of the Study Area is flat. The supply of domestic water for such key cities as Craiova and Slatina originates from artificial dams constructed in the Carpathian Mountains, and clean water produced by local forests is hardly used except for watering domestic vegetable gardens in some villages. Local people living near forests use well water to meet their daily water needs. While wells in and around forests show little fluctuation of the water level even in a year of drought, those located far from forests have dried up in the past, making their users understand the water retention function of forests.

The soil conservation function of forests is also not well recognised by local people, because of the generally flat terrain of the Study Area. However, this function is recognised by people living near specific areas where landslides have occurred in the past, or where the land has been devastated. People living along such large rivers as Danube River and Olt River are aware of this function, because of their past experience of soil erosion at the time of flooding and also because of their observation of the mitigation of soil erosion by the riverside forests. In areas of sandy soil in the south, people are aware of the windbreaking as well as soil conservation effects of forests, because forests prevent flying sand caused by strong wind. In some areas, R. pseudoacacia, Elaeagnus angustifolia, Populus spp. and Quercus spp. have been planted to benefit from these forest functions.

There is an increasing trend of utilizing beautiful forest landscape for recreational purposes as well as for tourism as shown in Table 2-3-1. While local people have been the main visitors to forests so far to enjoy picnics, the development of the road network in the Middle Part due to advancement of the motorization of Romanian society has prompted an increased number of visitors to forests for recreational purposes. There is a good prospect of the emergence of commercial activities on the green tourism, making the best use of the natural combination of rivers, lakes, forests, ranches and farms, and also agro-tourism through which tourists can experience farming in the future.

2.4.7 Forestry Work and Forest Management

(1) Past and Present Measures

1) Forest Decline Improvement Measures

Annual survey guidelines have been established in Europe to evaluate forest conditions using five grades (0 to 4) based on the degree of defoliation and

discolouration. These guidelines were first introduced in Germany in 1983 and are now accepted by many European countries. Romania is one such country using the guidelines for judgement of the state of forest decline and decisions on pest control measures and the cutting of declined trees. In addition to the application of these guidelines, the occurrence rate of damaged trees in stands is surveyed with a view to classifying the damage in each stand in one of four grades.

Efforts to deal with declined forests so far have concentrated on the cutting of damaged trees and planting at felling sites. These two activities have been employed for stands where the ratio of damaged trees is 65% or more. Unfortunately, however, the subsequent growth of the planted trees has not been very favourable due to the increasingly dry climate and soil, etc.

The RNP has been experimenting with various planting methods. A typical attempt can be seen at Letca in the area under the jurisdiction of the Ghimpati Forest Range Office of the Giurgiu Forest Branch Office where the following methods are being used under a joint research project with the ICAS.

- ① Direct seeding at felling sites of damaged trees in stands
- ② Clear cutting of damaged stands, followed by deep ploughing and seeding in planting holes
- 3 Clear cutting of damaged stands, followed by removal of the stumps by tractor, deep ploughing and straight line seeding
- ① Clear cutting of damaged stands, followed by removal of the stumps by tractor, deep ploughing and planting of seedlings
- ⑤ Clear cutting of damaged stands, followed by removal of the stumps by tractor, deep ploughing and planting of seedlings after use of the land for farming for one year

Of these sites, those where methods (4) and (5) are used show favourable growth of the planted trees. Deep ploughing has increased the porosity of the soil, improving the permeability. However, deep ploughing is very expensive and further research is in progress to develop new methods. The conditions of the soil at planting sites where method (4) is employed are discussed further in 2.6.1.
